Abstract

Adhesion GPCRs (aGPCRs) are difficult to study because they are activated by mechanical force. aGPCRs are autoproteolytically cleaved into N-terminal and C-terminal fragments. Mechanical force removes the N-terminal fragment revealing a tethered ligand activating the receptor. Proteinase Activated Receptors (PARs) are N-terminally cleaved by proteinases revealing a tethered ligand activating the receptor. We hypothesized the tethered ligand of aGPCRs could be revealed by replacing the N-terminal fragment with a PAR N-terminus. We fused the PAR2 N-terminus to the C-terminal fragments of four aGPCRs: CD97, EMR2, GPR56, and BAI1. PAR2-aGPCR chimeric receptors dose dependently recruited G-proteins and β -arrestins, supporting our hypothesis. Peptides made to mimic the tethered ligand, are sufficient to activate receptors. We developed a method for predicting aGPCR tethered ligand mimicking peptides and tested the approach for CD97. We found SSFAILMAH-NH₂ to be a potent CD97 activating peptide. In this thesis we developed two novel methods for studying the illusive aGPCRs.

Keywords

G-protein coupled receptor (GPCR), adhesion GPCR (aGPCR), CD97 (ADGRE5), EMR2 (ADGRE2), GPR56 (ADGRG1), BAI1 (ADGRB1), PAR2, Chimeric receptor, G-protein, β -arrestin

Summary for Lay Audience

The various systems of our bodies are controlled through an intercellular communication network mediated by soluble chemical messengers. These chemical messengers relay information throughout our bodies by binding receptors expressed on the surface of our cells. Exogenous molecules, drugs, can be made to mimic these chemical messengers, which can then bind cell surface receptors to modulate bodily functions and treat disease. G-protein coupled receptors (GPCRs) are the largest targets of FDA approved drugs, with around 25-36% of all FDA approved drugs targeting GPCRs. Despite this fact, the second largest GPCR subfamily, the adhesion GPCRs (aGPCRs), are not targeted by a single FDA approved drug. These receptors are attractive drug targets as they have been shown to be involved in brain development, the immune system, inflammatory diseases, and many different cancers. Lack of drug development at these receptors stems from the fact that they are activated in a two-cell system by mechanical force. As their mechanism of action is very difficult to reproduce and control in a laboratory setting, in this thesis we set out to design tools to enable their study. We designed a method in where aGPCRs could be activated by proteolytic cleavage instead of mechanical force, allowing receptor activation to be controlled by adjusting the concentration of enzyme. Further, we determined a method of predicting aGPCR agonist peptides. We then tested our two new methods on four of the more well studied aGPCRs: CD97 (ADGRE5), EMR2 (ADGRE2), GPR56 (ADGRG1), and BAI1 (ADGRB1). Both methods proved to be very effective and based on our result we believe they can be applied to study the whole family of 33 aGPCRs.

Co-Authorship Statement

All data presented in this thesis was completed by Victor Mirka in the laboratory of Dr. Rithwik Ramachandran. Dr. Rithwik Ramachandran provided guidance on experimental design, data analysis, interpretation, and manuscript preparation for all chapters.

Chapter 1:

Chapter 1 contains components of a book chapter in press written by Victor Mirka and Dr. Rithwik Ramachandran. Victor Mirka contributed to all figures, tables, and manuscript preparation.

Mirka V, Ramachandran R. (2021) Allosteric modulation of tethered ligand activated receptors. ELSEVIER. In press.

Chapter 2 and 3:

Dr. Arundhasa Chandrabalan completed all peptide synthesis with design directions from Victor Mirka and Dr. Rithwik Ramachandran. Victor Mirka completed all bioluminescence resonance energy transfer, TANGO, and confocal experiments described with guidance from Dr. Arundhasa Chandrabalan, Dr. Pierre Thibeault, and Dr. Rithwik Ramachandran.

Chapter 3 contains components of a book chapter in press written by Victor Mirka and Dr. Rithwik Ramachandran. Victor Mirka contributed to all figures, tables, and manuscript preparation.

Mirka V, Ramachandran R. (2021) Allosteric modulation of tethered ligand activated receptors. ELSEVIER. In press.

Acknowledgments

First, I would like to thank my supervisor Dr. Rithwik Ramachandran. In my fourth year you took a risk on me as a thesis student as I didn't have any prior hands-on lab experience. This one-year commitment quickly turned into three, and I have nothing but positive things to say about my experience in your lab. Your unique approach of allowing every student in your lab to choose their own project I feel brings out the best in people.

Next, I would like to thank the current and past members of the Ramachandran lab: Dr. Arundhasa Chandrabalan, Dr. Hiroyuki Igarashi, Dr. Pierre Thibeault, Samantha Ingham, Junbo Wang, Varunaavee Sivashanmugathas, and Darsh Shah. All of your guidance over the past three years has been greatly appreciated.

Finally, I would like to thank my Parents and brother. Without your continued support nothing that I have achieved would be possible.

VIP	Vasoactive intestinal peptide
W	Tryptophan
WNT	Wingless/Int-1
Y	Tyrosine

Chapter 1

1 Introduction

1.1 Regulation of cellular signaling

Multicellular organisms require efficient intercellular communication to control cellular proliferation, migration, differentiation, survival and homeostasis¹. Cells can communicate through direct cell-cell and cell-matrix interactions or through secreted signaling molecules^{1,2}. The interaction of E-cadherin with the epidermal growth factor receptor (EGFR) is an important example of direct cell-cell signaling^{3,4}. The homophilic interaction of two E-cadherin molecules on neighboring cells allows E-cadherin to interact with and inhibit the kinase function of the EGFR^{3,4}. EGFR kinase signaling is an important cell proliferation pathway and is often dysregulated in cancer^{3,4}.

A major component of intercellular signaling is mediated by the diffusion of chemical messengers, which act on cell surface receptors leading to intracellular changes¹. The signaling of secreted molecules can be differentiated based on the distance the signal must travel^{1,2}. In autocrine signaling, a secreted signaling molecule acts back on the same cell that produced it^{1,2}. For example, after a T cells has recognized its appropriate major histocompatibility complex (MHC)-peptide antigen complex it begins to release interleukin 2 and express high affinity interleukin 2 receptors⁵. This autocrine interleukin 2 signaling is important for initiating the clonal expansion of activated T cells for the future coordination of the adaptive immune response⁵.

When a cell releases a signaling molecule which then acts on a nearby cell, this is considered paracrine signaling^{1,2}. An example of paracrine signaling is when neurotransmitters released from the nerve terminal of one neuron cross the synaptic cleft and act on the receptors of post synaptic neurons². In Parkinson's disease, degeneration of dopaminergic neurons in the substantia nigra causes the loss of important inhibitory dopamine paracrine signaling in the neostriatum, leading to involuntary movements⁶.

Endocrine signaling occurs when a signaling molecule is secreted into the circulation and acts on a distant cell^{1,2}. The release of thyroid stimulating hormone (TSH) from the anterior pituitary, which then travels through the circulation to bind TSH receptors on thyroid follicular cells is an example of endocrine signaling⁷. TSH signaling at thyroid follicular cells is an important regulator of thyroid hormone production, and its dysregulation commonly results in cancer⁷. Exogenous molecules, drugs, can be made to mimic these endogenous chemical messengers to modulate homeostatic processes². Many disease states are the result of homeostatic dysregulation and can therefore be treated by the use of exogenous drugs⁸.

1.2 Major receptor families

Cellular receptors can be broadly separated into four families: ligand gated ion channels, enzyme-linked receptors, intracellular receptors, and G-protein coupled receptors⁹. As G-protein coupled receptors were the primary focus of this thesis they will be explained in detail and only a brief description will be provided for the other three receptor families.

1.2.1 Ligand gated ion channels

Ligand gated ion channels are generally pentameric integral membrane proteins which form a ligand gated membrane spanning pore^{9,10}. Upon ligand binding the receptor undergoes a conformational change, opening the pore, and allowing the selective passive flow of ions down their electrochemical gradient across the plasma membrane^{9,10}. Of the four major receptor family's ligand gated ion channels have the shortest response durations, lasting only a few milliseconds^{9,10}. As an example, in post-natal neurons upon the binding of the neurotransmitter Gama-Aminobutyric acid (GABA), the GABA_A receptor opens a chloride selective channel¹¹. Chloride moving into the cell down its electrochemical gradient hyperpolarizes the cell, and this basic mechanism is the primary way inhibitory signaling is transduced in the brain¹¹. The balance of excitatory and inhibitory signaling in the brain is vital for homeostasis¹¹. Dysregulation of GABA_A receptors inhibitory signaling in the brain, can lead to an excess of excitatory signaling, resulting in diseases such as epilepsy¹¹.

1.2.2 Enzyme-linked receptors

Enzyme-linked receptors are generally single pass transmembrane proteins with an extracellular ligand binding domain and an intracellular region that either has intrinsic enzyme activity or associates directly with an enzyme^{9,12}. Upon ligand binding the receptor undergoes a conformational change that either activates the intrinsic enzyme or recruits one to its intracellular binding domain^{9,12}. The duration of enzyme-linked receptor response is generally on the scale of minutes to hours^{9,12}. Most enzyme-linked receptors fall under the category of receptor tyrosine kinases, where the receptor contains an intracellular kinase domain capable of phosphorylating itself and other effector proteins to initiate signaling cascades upon ligand binding^{9,12}. The insulin receptor is an example of a receptor tyrosine kinase, however unlike most it exists as a preformed dimer¹³. Upon insulin binding the two receptors intracellular kinase domains come in contact and begin to phosphorylate each other¹³. These phosphorylated tyrosine residues form docking site for other kinase effector proteins to continue the signaling cascade¹³. Dysregulated insulin receptor signaling is known to contribute to the development of diseases such as type 2 diabetes¹³.

1.2.3 Intracellular receptors

Intracellular receptors are located primarily in the cytoplasm and nucleus and are activated by cell permeant lipophilic ligands, such as hormones⁹. Unlike the other receptor families, intracellular receptors directly regulate gene expression by physically binding DNA and acting as transcription factors⁹. Upon ligand binding a prebound inhibitory protein is generally released, allowing receptor dimerization and translocation to the nucleus for DNA binding⁹. Because intracellular receptors primarily regulate changes in gene transcription their signaling duration is on the scale of hours to days⁹. The estrogen receptor can be an example of an intracellular receptor¹⁴. Upon estrogen binding the pool of intracellular estrogen receptors, the receptor undergoes a conformational change causing the release of inhibitory heat shock proteins, revealing of a DNA binding domain, and allowing receptor dimerization¹⁴. The dimerized receptors then translocate from the cytoplasm to the nucleus and bind the promoters of specific genes to positively or negatively regulate their expression¹⁴.

1.3 G-protein coupled receptors

G Protein-coupled receptors (GPCRs) are the largest family of membrane proteins in the human genome^{15,16} and have evolved to respond to diverse stimuli¹⁷. GPCRs are also major targets for therapeutic drugs with estimates showing between 25-36% of all FDA approved drugs targeting GPCRs¹⁸. These receptors are characterized by their extracellular N-terminus and ligand binding site, seven transmembrane spanning domains, and intracellular C-terminus and transducer binding site^{19,20}. Classically GPCR activation is triggered by the binding of a ligand to the extracellular ligand binding site, which induces conformational changes in the receptor that allows the intracellular binding of transducers, such as heterotrimeric G proteins and arrestins^{19,20} (Fig 1). The duration of signaling events produced by GPCRs are on the scale of seconds to minutes⁹.

Figure 1. General activation mechanism for most GPCRs. A ligand binds the receptor causing a conformational change, leading to receptor activation. The activated receptor is then able to recruit one or more of the five major families of effectors proteins G_{αs}, G_{αi/o}, G_{αq/11}, G_{α12/13}, and β-arrestin 1/2. The type of effect protein then determines the distinct change in cellular signaling that will occur. Figures were generated using the program Biorender (<https://biorender.com>).

1.3.1 Allosteric transitions

Allosteric transitions describe the change in receptor conformation from the inactive to active state. These events are best understood for Rhodopsin family (class A) GPCRs, as they have the most solved ligand and effector bound structures in various conformational states^{21,22}. The general structural changes involved in the allosteric transition to the active state are an outward movement of transmembrane domain 6 (TM6), an inward movement of TM5 and TM7, a rotation of TM3, a constriction of the orthosteric site, and an opening of an intracellular transducer binding site²¹⁻²⁵. These structural changes are mediated by a conserved set of microswitches including CWxP, NPxxY, PIF, and D(E)RY. Located in TM6, W^{6.48} (Ballesteros Weinstein numbering in superscript²⁶) of the CWxP motif in class A GPCRs is thought to function as a “toggle switch” between the inactive and active states^{22,24}. Located in TM7, the NPxxY motif stabilizes the inactive state of Rhodopsin family GPCRs by forming a hydrogen bond network, via N^{7.49}, with water molecules and an allosteric Na⁺ ion. Upon ligand binding, TM7 moves inward, and this hydrogen bonding network is broken. In the active state the NPxxY motif instead mediates the packing of TM3 to TM7²². The PIF motif, which is located in TM6, interacts with the toggle switch residue W^{6.48} to help mediate the outward movement of TM6 upon ligand binding²². Located in TM3, the D(E)RY motif, or ionic lock switch, stabilizes the inactive state by forming a salt bridge between R^{3.50} and E^{6.30} of TM6. Ligand binding breaks this salt bridge, allowing the outward movement of TM6²².

1.3.2 GPCR effector proteins

Interaction of the GPCR intracellular face with signaling effectors determines the second messenger signaling pathways that are activated to affect changes in cellular function²⁰. Five types of effector proteins cause the majority of signaling downstream of GPCRs^{19,27-30}. These are the four different types of heterotrimeric G-proteins and the β -arrestins^{19,27-30}. The heterotrimeric G-protein is made up of G α , G β and G γ subunits^{19,27,28}. The G β and G γ subunits exist as a dimer and are therefore usually referred to as G $\beta\gamma$ ^{19,27,28}. The G α subunit contains a GTPase domain and guanine nucleotide binding site, which in the inactive state is bound to GDP^{19,27,28}. The heterotrimeric G-protein is anchored at the plasma membrane by lipid modifications on the G α and G γ subunits; however, whether

the heterotrimeric G-protein is pre-coupled to the receptor seems to be receptor and G-protein dependent^{19,27,28}. Although there are many different types of G_α , G_β and G_γ subunits, the different families of heterotrimeric G-protein are characterized by the type of G_α subunit^{19,27,28}. The four different families of G-proteins are G_s , $G_{i/o}$, $G_{q/11}$, and $G_{12/13}$. Although cross talk between pathways occurs, each type of G-protein generally employs different effector proteins to cause distinct changes in cellular function. The primary function of GPCRs is to act as guanine nucleotide exchange factors (GEFs) for heterotrimeric G-proteins, where the pre-bound GDP on the G_α subunit is exchanged for GTP^{19,27,28}. This exchange activates the G-protein, causing dissociation of the G_α subunit from $G_{\beta\gamma}$, allowing both to engage downstream effectors proteins^{19,27,28}. Signaling via the G_α subunit is terminated by both its own low activity GTPase and by effectors such as regulators of G-protein signaling (RGS) proteins, which act as GTPase accelerating proteins (GAPs)^{19,27,28}. The inactive G_α subunit then binds up free $G_{\beta\gamma}$ subunits to terminate its signaling and reform the heterotrimeric G-protein for future signaling events^{19,27,28}.

1.3.2.1 The G_s family of G-proteins

The G_s (stimulatory) family of alpha subunits includes $G_{sS}(\text{short})$, $G_{sL}(\text{Long})$, and $G_{olf}(\text{olfactory})$ ^{27,28}. $G_{sL}(\text{Long})$ is a splice variant from the same gene as $G_{sS}(\text{short})$ that contains a longer N-terminal region^{27,28}. G_{sS} is ubiquitously expressed, whereas the expression of G_{sL} and G_{olf} are restricted to neuroendocrine cells and the olfactory epithelium, respectively^{27,28}. Once activated, the primary effector protein activated by the G_s family is adenylyl cyclase^{27,28}. Adenylyl cyclase converts ATP into the second messenger signaling molecule cyclic AMP^{27,28} (cAMP). Therefore, a common method of determining G_s activation is to measure an increase in cellular cAMP levels. cAMP can then activate protein kinase A (PKA), which can phosphorylate a number of downstream effector proteins^{27,28}. Cyclic AMP response element binding protein (CREB) is an important transcription factor that when activated by PKA can increase the expression of genes involved in cell proliferation, survival and differentiation^{27,28}. Therefore, another common way of determining G_s activation is measuring the activity of a luciferase

reporter gene under the control of CREB³¹. cAMP can also open cation ligand gated ion channels in the olfactory epithelium^{27,28}.

1.3.2.2 The $G_{i/o}$ family of G-proteins

The $G_{i/o}$ (inhibitory/other) family of G-proteins consists of G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{gustducin}$, $G_{transducin-r(rod)}$, and $G_{transducin-c(cone)}$ ^{27,28}. G_{i1} and G_{i2} are widely distributed while G_{i3} is ubiquitously expressed^{27,28}. The expression of G_{oA} and G_{oB} are restricted to neurons and neuroendocrine cells, respectively^{27,28}. G_z expression is restricted to neurons and platelets, whereas $G_{gustducin}$ is expressed in taste cells and intestinal brush boarder cells^{27,28}. $G_{transducin-r}$ is expressed in retinal rod cells and taste cells, while $G_{transducin-c}$ is expressed in rental cone cells^{27,28}. Opposite to G_s , G_{i1-3} inhibit the activity of adenylate cyclase to reduce cellular concentrations of cAMP. Therefore, a common method of determining $G_{i/o}$ activation is to measure decreases in intracellular cAMP levels. The signaling of G_{oA} and G_{oB} is generally thought to occur through their $G_{\beta\gamma}$ subunit, which can activate G-protein regulated inward rectifier potassium channels (GIRKs) and inhibit voltage dependent calcium channels^{27,28}. Due to the high expression of $G_{i/o}$ family G-proteins (especially G_o), they are thought to be the primary G-proteins which signal through their $G_{\beta\gamma}$ subunit^{27,28}. Unlike other members of the G_i subfamily, G_z and $G_{gustducin}$ can reduce cellular levels of cAMP by activating cAMP specific phosphodiesterase, which catalase the breakdown of cAMP^{27,28}. G_z can also inhibit adenylate cyclase to decrease cAMP levels, and interestingly unlike G_{i1-3} this inhibition is pertussis toxin insensitive^{27,28}. Similar to G_z and $G_{gustducin}$, $G_{transducin-r}$ and $G_{transducin-c}$ inhibit the production of a cyclic second messenger by activating a phosphodiesterase, however, they inhibit the production of cyclic GMP through the activation cGMP specific phosphodiesterase^{27,28}.

1.3.2.3 The $G_{q/11}$ family of G-proteins

The $G_{q/11}$ subfamily contains of G_q , G_{11} , G_{14} , G_{15} , and G_{16} . G_q and G_{11} show ubiquitous expression, whereas G_{14} expression is restricted to the kidney, lung, liver, and spleen^{27,28}. G_{15} is the murine homolog whereas G_{16} is the human, and shows expression restricted to hematopoietic cells^{27,28}. The primary effector activated by the $G_{q/11}$ family of G-proteins is phospholipase $C\beta$ (PLC- β), which cleaves the signaling membrane lipid

phosphatidylinositol 4,5-bisphosphate (PIP₂) into inositol triphosphate (IP₃) and diacylglycerol (DAG)^{27,28}. IP₃ can then open ligand gated ion channels on the endoplasmic reticulum (ER) to increase levels of intracellular calcium^{27,28}. Therefore, a common method of determining G_{q/11} activation is measuring changes in intracellular calcium levels. The calcium released from the ER can then act back upon ER calcium channels to further increase intracellular calcium levels, a process known as calcium induced calcium release^{27,28}. Increased levels of intracellular calcium can then go onto activate a host of different effector proteins, such as the transcription factor nuclear factor of activated T-cells (NFAT)^{27,28}. Therefore, another common way of determining G_{q/11} activation is measuring the activity of a luciferase reporter gene under the control of NFAT³¹. DAG remains associated with the plasma membrane, where it is able to activate effector proteins such as protein kinase C (PKC)^{27,28}. Through the binding of intracellular calcium molecules and DAG, PKC becomes fully activated and is able to phosphorylate various effector proteins^{27,28}.

1.3.2.4 The G_{12/13} family of G-proteins

The G_{12/13} subfamily consists of just G₁₂ and G₁₃, both of which show ubiquitous expression^{27,28}. Once activated the G_{12/13} family of G-proteins generally activate the effector protein RhoGEF1, which exchanges GDP for GTP on RhoA^{27,28,32}. RhoA is then able to bind and activate Rho-associated protein kinase (ROCK), which phosphorylates a number downstream cytoskeletal effector proteins involved in cell movement and shape change^{27,28,32}. RhoA/ROCK can also activate the transcription factor serum response factor (SRF) which binds genes with serum response elements (SRE) to control processes such as cell growth and survival³¹. Therefore, common methods of determining G_{12/13} activation are measuring the activity of RhoA and the activity of a luciferase reporter gene under the control of SRF³¹.

1.3.2.5 The β-arrestin family of proteins

At the level of the receptor, signaling is terminated through receptor desensitization and internalization^{29,30,33,34}. Serine and threonine residues on the receptors C-terminus can be phosphorylated by G-protein coupled receptor regulator kinases (GRKs), and through

negative feedback by PKA and PKC^{29,30,33,34}. These phosphorylated residues become binding sites for the β -arrestins. The four types of β -arrestin are arrestin 1, arrestin 4, β -arrestin 1 (arrestin 2), and β -arrestin 2 (arrestin 3)²⁹. The expression of the visual arrestins, arrestin 1 and arrestin 4, are restricted to rod and cone cells, respectively, whereas β -arrestin 1 and β -arrestin 2 are expressed ubiquitously²⁹. The binding of β -arrestin blocks G-proteins from binding the receptors intracellular transducer site, therefore uncoupling the receptor from G-protein dependent downstream signaling^{29,30,33,34}. Adaptor protein 2 (AP-2) and clathrin bind β -arrestin and direct the receptor to clathrin coated pits^{33,34}. Dynamin activation then causes internalization of the receptor-clathrin complex into endosomes^{33,34}. The receptor can either be recycled to the membrane for future signaling events or sent to the lysosome for degradation^{33,34}. β -arrestin can also cause G-protein independent receptor signaling by acting as a docking scaffold for effector proteins such as extracellular receptor kinase/mitogen activated protein kinase (ERK/MAPK), which can phosphorylate a number of transcription factors which control the expression of genes involved in cell proliferation, differentiation, and survival^{29,30,33,34}.

1.3.3 Major GPCR subfamilies

GPCRs can be separated into four major subfamilies: class A rhodopsin-like, class B secretin-like/adhesion, class C metabotropic glutamate-like, and class F frizzled/smoothened³⁵. Alternatively, they can be categorized in a similar way using the GRAFS system: Glutamate, Rhodopsin, Adhesion, Frizzled, Secretin³⁵. The major difference in these naming systems being the separation of the two types of class B receptors, secretin and adhesion, into two different subfamilies in the GRAFS system, likely due to the difference in activation mechanism. Both systems are often used in GPCR literature, therefore when explaining the different subfamilies of GPCRs both systems will be referenced for clarity.

1.3.3.1 Class A rhodopsin-like receptors

The class A rhodopsin-like receptors are by far the largest GPCR subfamily, with around 719 members separated into three major subfamilies¹. Receptors in the first subfamily

utilize a ligand binding site deep within their transmembrane domains to bind small molecule ligands such as neurotransmitters, signaling lipids, and odorants¹. Subfamily 2 binds mainly protein ligands such chemokines and tethered ligands through a more exposed binding site which includes the extracellular loops¹. Tethered ligands will be discussed in detail in following sections on proteinase activated receptors and adhesion GPCRs. Subfamily 3 utilizes its larger extracellular region to bind lower weight hormones such as luteinizing hormone (LH), follicle stimulating hormone (FSH), and thyroid stimulating hormone¹.

1.3.3.2 Class B secretin-like/adhesion receptors

Class B secretin-like/adhesion receptors are characterized by their extremely large extracellular regions, which are often larger than the membrane imbedded and intracellular receptor regions^{1,36}. These receptors can be separated into two major subfamilies based on mechanism of action. Through their large extracellular regions, subfamily B1 secretin-like receptors can bind the C-terminus of high molecular weight peptides hormones such as secretin, glucagon, and vasoactive intestinal peptide (VIP)^{1,36}. This interaction allows the peptide hormones N-terminus to adopt a α -helical structure and interact strongly with a transmembrane domain binding site leading to receptor activation³⁶. This process is known as the two-domain model of activation for class B receptors³⁶. Subfamily B2 adhesion receptors large extracellular regions are removed by mechanical force through the binding of various transmembrane and extracellular matrix proteins such as integrins, collagen, and sugars³⁷. Removal of the extracellular region then reveals a tethered ligand similar to the mechanism of proteinase activated receptors³⁷, which are discussed in detail in the section 1.4.

1.3.3.3 Class C metabotropic glutamate-like receptors

The family of class C receptors contains members such as the metabotropic glutamate receptors, GABA_B receptors, taste receptors, and calcium sensing receptor (CaSR)^{1,38}. These receptors utilize a unique mechanism of action, where an extracellular Venus flytrap (VFT) domain is used to bind ligands³⁸. The two lobed VFT domain remains open until ligand binding, where it undergoes a conformational change to a closed position

which brings the lobes closer together leading to receptor activation³⁸. Although the other families of GPCRs can form various combinations of homo and heterodimers, for class C metabotropic glutamate-like receptors dimerization is a requirement for receptor activation^{1,38}.

1.3.3.4 Class F frizzled/smoothed receptors

The frizzled and smoothed receptors make up the class F subfamily of GPCRs^{1,39-41}. These receptors are important regulators of development and are therefore often dysregulated in cancer^{1,39-41}. The ligands of the frizzled receptors are the 19 different wingless/Int-1 (WNT) family of proteins^{39,40}. WNT proteins bind a cysteine rich domain (CRD) on the extracellular region of frizzled receptors using both their lipid modified thumb and index finger domains^{39,40}. The activation of frizzled receptors by WNT proteins also require the recruitment of lipoprotein receptor related protein (LRP) co-receptors^{39,40}. Under resting conditions, smoothed receptors are inhibited by the 12 transmembrane domain protein Patch^{39,41}. Upon binding of the hedgehog family of proteins to the hedgehog receptor, Patch, it is internalized and degraded^{39,41}. The loss of patch inhibition is sufficient for smoothed receptor activation; however, the CRD domain binding ligand oxysterol and transmembrane domain binding smoothed ligand (SAG) can contribute to great levels of receptor activation^{39,41}.

1.4 Tethered ligand activated GPCRs

While GPCRs ligands are diverse, for the most part they are soluble molecules, such as hormones or neurotransmitters, that diffuse freely and find their cognate receptors⁴². An exception to this rule is in instances where the ligand is physically attached to the receptor. Such ligands are often referred to as tethered ligands or tethered agonists and are an example of a non-classical GPCR activation mechanism, due to the irreversible nature of such receptor activation. There are two prominent examples of GPCR families that can be activated by tethered ligands, the first are the four-member family of Proteinase Activated Receptors (PARs)⁴³ and the other is the adhesion family of GPCRs (aGPCRs)⁴⁴. In the case of both PARs and aGPCRs the receptors contain within their sequence a receptor activating motif that is masked in the inactive receptor and unmasked

by activators to reveal the tethered ligand. The tethered ligand binds the orthosteric site intramolecularly to trigger signaling^{45,46} (Fig 2, Fig 3, and Fig 4).

Figure 2. PAR receptor mechanism of activation. Proteinases, such as trypsin and thrombin, are able to cleave the receptors N-terminus revealing a normally hidden tethered ligand which then binds and activates the receptor. Figures were generated using the program Biorender (<https://biorender.com>).

Figure 3. Basic structure of an adhesion GPCR. The receptors N-terminal fragment remains strongly non-covalently associated with the membrane imbedded C-terminal fragment. When mechanical force is applied to the N-terminal fragment these non-covalent interactions are broken and the two fragments separate. Figures were generated using the program Biorender (<https://biorender.com>).

Figure 4. Adhesion GPCR mechanism of activation. Adhesion GPCR endogenous ligands tend to be transmembrane and extracellular matrix proteins. When expressed on neighboring cells these proteins can bind the N-terminal fragment and induce mechanical force. Once the N-terminal fragment is removed a normally hidden tethered ligand is able to bind and activate the receptor. Figures were generated using the program Biorender (<https://biorender.com>).

1.4.1 Proteinase Activated Receptors (PARs)

The PAR family is made up of 4 class A Rhodopsin like GPCRs: PAR1, PAR2, PAR3, and PAR4⁴³. Because of their importance in platelet function and inflammation, PARs are exciting targets for new anti-thrombotic and anti-inflammatory agents. The tethered ligands of PARs are encoded in their N-termini. Various proteinases are able to cleave specific sites on the PAR N-terminus, revealing tethered ligands capable of binding the orthosteric site and activating receptor signaling (Fig 2)^{47,48}. PAR1, PAR3 and PAR4 N-termini contain thrombin cleavage sites (R41/S42 for PAR1, K38/T39 for PAR3 and R47/G48 for PAR4) which reveal the canonical tethered ligands SFLLRN...., TFRGAP.... and GYPGQV.... respectively, while PAR2 is N-terminally cleaved by trypsin at R35/S36, revealing the SLIGKV.... tethered ligand. The tethered ligands in all cases bind intramolecularly and in the case of PAR1, PAR2 and PAR4 activate receptor coupled second messenger signaling cascades⁴⁸. The ability of PAR3 to signal independently has been questioned and this receptor may primarily act as a co-factor for other PARs⁴⁹.

Despite being activated by this unusual proteolytic mechanism, PARs are fundamentally peptide receptors and the ability of synthetic peptides to act as surrogate activators of the PARs was made soon after their discovery. Short 5-6 amino acid synthetic peptides have now been developed for PAR1 (TFLLR-NH₂), PAR2 (SLIGRL-NH₂) and PAR4 (AYPGKF-NH₂) allowing specific activation and study of individual PARs, particularly in cells that express multiple members of this family that respond to a common activating enzyme. Peptides mimicking the PAR3 tethered ligand (TFRGAP-NH₂) activate PAR1 and PAR2⁴⁸.

1.4.2 Adhesion GPCRs (aGPCRs)

1.4.2.1 Tethered ligand mediated signaling

aGPCRs are a family of 33 receptors which are further divided into 9 subfamilies^{46,50,51}. With GPCRs being such a major target of FDA approved drugs, one would assume all the major subfamilies are involved in current drug development. Surprisingly the second largest GPCR subfamily, the adhesion GPCRs (aGPCRs), are not currently targeted by a

single FDA approved drug⁵². These receptors are dysregulated in many cancers, neurological disorders, and inflammatory diseases⁵³⁻⁵⁶. An absence of drug development at these receptors can be explained by their unusual structure and mechanism of action (Fig 3 and Fig 4)⁵⁷. Similar to PARs, many aGPCRs can be activated by tethered ligands encoded in their N-termini⁴⁶. The mechanism by which the aGPCR tethered ligand is revealed is however distinct from the PARs. aGPCRs are autoproteolytically cleaved at a GPCR autoproteolysis site (GPS) within their GPCR autoproteolysis inducing domain (GAIN) during endoplasmic reticulum biosynthesis and trafficking to the cell membrane⁵⁰. The resulting N-terminal fragment (NTF) of the receptor remains non-covalently associated to the membrane imbedded C-terminal fragment (CTF)⁵⁰. Mechanical force applied to the NTF enable its removal, revealing the tethered ligand (sometimes referred to as the *stachel*) in the CTF, which binds intramolecularly to activate receptor signaling^{50,57}. The NTF of aGPCRs are large and diverse, encoding binding sites for various molecules, such as transmembrane and extracellular matrix proteins⁵⁰. As an example, GPR56 (ADGRG1) was recently shown to be the collagen receptor in platelets. Type III collagen tethered to the extracellular matrix binds the NTF of GPR56⁵⁸. As the affinity for the interaction of collagen to the extracellular matrix is stronger than the non-covalent forces tethering the two receptor fragments, the NTF of GPR56 is removed, revealing the tethered ligand, TYFAVLM...⁵⁹, which then binds the orthosteric site and activates receptor signaling.

As with the PARs, synthetic peptides mimicking the tethered ligand are also able to activate aGPCRs. Peptide libraries based on the aGPCR stalk region (beginning of CTF to TM1) of many aGPCRs have been studied to show the utility of these peptides and to provide further support for tethered agonism as an activation mechanism common to many aGPCRs⁵⁹⁻⁶¹. The consensus from these studies is that the first 7 amino acids of the CTF, which are highly conserved, likely form the core tethered ligand (consensus sequence = TXFAVLM). However, for many aGPCRs such 7 amino acid peptides are not agonistic. It is thought that predicted turn elements in many aGPCR stalk regions that lie outside of core sequence have important roles in conferring agonistic properties. This is illustrated nicely when comparing GPR56, which has no predicted stalk region turn elements, and is activated by a peptide consisting of the first 7 CTF amino acids,

TYFAVLM to GPR110 (ADGRF1), which has many predicted stalk region turn elements, and is only activated by longer peptides containing these turn elements⁵⁹.

1.4.2.2 Tethered ligand independent signaling

Although tethered ligand mediated signaling is thought to be their primary mechanism of action, there is evidence that adhesion GPCRs can be activated in a tethered ligand independent manner^{46,62-65}. Ligands binding to allosteric regions of the NTF are able to induce conformational changes leading to receptor activation. Signaling through the BAI1 (ADGRB1) receptor, synaptamide and monobodies targeting the GAIN and Pentraxin/Laminin/neurexin/sex hormone binding globulin-like (PLL) domains of the NTF are the best examples of such mechanisms⁶²⁻⁶⁴. Recently, aGPCRs have also been shown to be activated by more classic allosteric modulation mechanisms. Glucocorticoids allosterically binding the 7 transmembrane bundle of GPR97 (ADGRG3) and inducing conformation changes leading to receptor activation, is so far the only example of such a mechanism⁶⁵.

A truncation of the BAI1 receptor, where the entire extracellular region up until the first transmembrane domain was removed showed no decrease in activity compare to both full length receptor and truncated receptors where the proposed tethered ligand was exposed⁶². If tethered agonism was its mechanism of activation, then this truncation should have drastically decreased its activity⁶². This would suggest that upon removal of BAI1's N-terminal fragment the receptor undergoes a conformational change to a more active state to initiate signaling.

Synaptamide is an endogenous metabolite of the omega-3-fatty acid Docosahexaenoic acid (DHA) that was recently shown to activate the aGPCR GPR110^{64,66}. Synaptamide activation of GPR110 induces G_s mediated changes in cAMP, increasing neurogenesis, synaptogenesis, and neurite growth^{64,66}. Neither mutation preventing GAIN domain cleavage, H565 to A, or tethered ligand activity, T567 to A, were shown to effect synaptamide mediated GPR110 signaling⁶⁴. Synaptamide was also shown to not affect orthosteric tethered ligand mediated signaling, therefore it is an allosteric agonist and not a positive allosteric modulator (PAM)⁶⁴. Using chemical crosslinking, mass spectrometry,

and molecular modeling synaptamide was found to bind a long channel between subdomains A and B of the GAIN domain⁶⁴. Modeling predicts this binding site to have a polar exposed region and a hydrophobic core⁶⁴. Mutation of predicted synaptamide interacting residues Q511, N512, Y513 to alanine decreased synaptamide mediated changes in cAMP and double mutations of Q511/N512 and N512/Y513 to alanine completely abolished synaptamide induced signaling⁶⁴. These interacting residues are however not conserved in other closely related aGPCRs⁶⁴. Also, the interface between subdomains A and B is much smaller in structures of other aGPCR N-terminal fragments^{59,64}. Future work is needed to determine if other aGPCRs utilize a similar allosteric GAIN subdomain interface binding site.

Monobodies are synthetic proteins based on the human fibronectin type-III scaffold that have been used extensively to help stabilize proteins for structural studies. Monobodies created to determine the crystal structure of GPR56's N-terminal fragment were found to act as both allosteric agonists and inverse agonists⁶³. The $\alpha 5$ monobody, which targets both the GAIN and PLL domains of mouse GPR56, is an allosteric inverse agonist that inhibits SRE reporter gene signaling below baseline levels⁶³. Similarly, the $\beta 1$ monobody is an allosteric inverse agonist that targets both the GAIN and PLL domains and inhibits SRE reporter gene signaling below baseline but targets human GPR56⁶³. The $\beta 7$ monobody targets only the PLL domain of human GPR56 and acts as an allosteric agonist by increasing SRE reporter gene signaling above baseline levels⁶³. Neither mutation preventing GAIN domain cleavage or tethered ligand function affected the signaling of these monobodies⁶³. Therefore, these monobodies act as allosteric agonists and inverse agonists and not as negative allosteric modulators (NAMs) or PAMs. In the future, designing monobodies targeting the GAIN and PLL domains of other aGPCRs could enable the study of structure and signaling for many orphan aGPCRs.

Recently, GPR97 was found to be activated by several different glucocorticoids⁶⁵. Prednisolone, dexamethasone, beclomethasone, prednisone, cortisol, cortisone, and 11-deoxycortisol were all shown to increase GPR97 mediated $G_{i/o}$ signaling⁶⁵. Beclomethasone and cortisol were able to activate C-terminal fragment only GPR97 8-30 times more than full length receptor⁶⁵. This observation suggests glucocorticoids function

as ago-PAMs of GPR97. Ago-PAMs are defined as allosteric modulators that have activity with and without the presence of orthosteric agonists. Structures of beclomethasone and cortisol bound to GPR97 determined a long ellipsoidal shaped allosteric binding site within the 7 transmembrane domain bundle created by residues from TM1-3, TM5-7, ECL2, and ECL3⁶⁵. Therefore, glucocorticoids seem to activate GPR97 like more conventional allosteric modulators. Mutations of glucocorticoid interacting residues Y406, W421, L498, F345, W490, I494, and N510 to alanine all decreased cortisol and beclomethasone mediated GPR97 $G_{i/o}$ signaling⁶⁵. Interestingly, 7/14 residues involved with glucocorticoid binding to GPR97 are conserved across the G subfamily, and 5/14 are conserved across all aGPCRs⁶⁵. This suggests other aGPCRs may share a similar allosteric site, and that other members of the G family may also bind glucocorticoids. A previous small molecule library screen of another G subfamily member, GPR56, identified 3- α -acetoxydihydrodeoxydunin (3- α -DOG) as a partial agonist⁶⁷. Glucocorticoids and 3- α -DOG share a similar 4 ring steroid-like structure. This further supports the idea that other G subfamily members may share a similar allosteric site that interacts with steroid-like molecules.

1.5 aGPCRs of interest

In this thesis we chose to design tools for studying the four aGPCRs CD97, EMR2, GPR56, and BAI1. We chose these four receptors as they are four of the more well studied members of the family and because they are involved in physiological processes and diseases that are of particular interest to our lab.

1.5.1 CD97 (ADGRE5)

Cluster of differentiation 97, CD97 (ADGRE5), is part of the E subfamily and was one of the first aGPCRs to be discovered in the early 1990's⁶⁸. CD97's known endogenous ligands are CD55/decay accelerating factor, CD90/thymocyte differentiation antigen 1, chondroitin sulfate B, and integrins $\alpha_v\beta_3$ and $\alpha_5\beta_1$ ⁵⁰. CD97 has been shown to be expressed in the bone, hematopoietic cells, heart, lungs, intestine, pancreas, kidney, bladder, uterus, skeletal muscle, epididymis, and adipocytes^{50,69}. This receptor has been shown to be involved in immune cell function, gut epithelial cell biology, and many

different cancers^{53,55,56,70-74}. A single nucleotide polymorphism (T64C) in the CD97 promoter has been associated with the development of colitis⁷¹. Further, the CD97 gene is part of an inflammatory bowel disease susceptibility locus on chromosome 19^{75,76}. When CD97 was overexpressed in a mouse model of colitis, there was an attenuation of the disease and an apparent protection from the development of colorectal cancer⁷¹. The colonic cells of mice overexpressing CD97 were shown to have increased lateral cell-cell junctions⁷¹. As colitis is a disease that damages the colonic epithelial barrier, it was hypothesized that CD97 signaling may have increased colonic lateral cell contacts resulting in the apparent protection from the disease⁷¹. Colonic cells from mice overexpressing CD97 also had significantly more membrane associated β -catenin⁷¹. β -catenin is normally a component of lateral cell junctions, but when the cellular barrier is compromised this protein internalizes and translocates to the nucleus to increase the expression of genes involved in colorectal carcinogenesis^{71,72}. CD97 has been shown to be involved in many innate and adaptive immune responses such as immune cell migration, proliferation, and mobilization from the bone marrow^{50,77-79}. Overexpression of CD97 leads to increased tumor proliferation, migration and invasiveness and poor clinical outcomes in various cancers including colorectal, hepatic, breast, thyroid, gastric and prostate^{53,55,56,70-74}.

1.5.2 EMR2 (ADGRE2)

Epidermal growth factor-like module-containing mucin like hormone receptor-like 2, EMR2 (ADGRE2), and CD97 were the first adhesion GPCRs to be discovered⁶⁸. Currently, the only known endogenous ligand for EMR2 is chondroitin sulfate B⁵⁰. As EMR2 is not expressed in mice it has been difficult to characterize its expression, however it is known to be expressed in the lungs, breast, brain, bone, and hematopoietic cells^{50,53}. This receptor is also a member of the E subfamily and is involved in immune cell functions, such as neutrophil migration, degranulation, and cytokine secretion^{50,80,81}. EMR2 has been shown to be overexpressed in various cancers such as lung, breast and brain^{50,53}.

1.5.3 GPR56 (ADGRG1)

Of the 33 adhesion GPCRs, G-protein coupled receptor 56 (GPR56) is probably the most well studied. This is likely due the fact loss of function mutations in GPR56 results in the rare hereditary congenital brain disorder bilateral frontoparietal polymicrogyria (BFPP)⁸²⁻⁸⁶. Patients with BFPP exhibit significant developmental and motor delay, seizures, ataxia, language and visual impairment⁸²⁻⁸⁶. GPR56 is vital in the development of the cerebral cortex, where by binding collagen III it guides newly formed neurons to stop migrating once they have reached the pial membrane⁸²⁻⁸⁶. Loss of function mutations in GPR56 causes the over migration of neurons through the pial membrane resulting in BFPP⁸²⁻⁸⁶. The known endogenous ligands of GPR56 are collagen III and transglutaminase II^{50,53}. In the brain GPR56 is expressed in oligodendrocytes, glia cells, microglia, and neural progenitor cells⁵⁰. GPR56 is also expressed in the bone, platelets, lymphocytes, Schwann cells, liver, thyroid, testis, intestines, prostate, skin, and skeletal muscle^{50,53}. Other than its important role in cerebral development, GPR56 was recently shown to be important for platelet activation⁵⁸. GPR56 knockout mice show a significant lack of hematopoietic stem cells in the bone marrow but an accumulation in the spleen, liver and peripheral blood⁸⁷. This suggests GPR56 has a role in immune cell compartmentalization, likely through binding adhesive molecules such as collagen III, keeping GPR56 expressing cells in the bone marrow. Male GPR56 knockout mice were found to be infertile due to improper testicular basal lamina formation leading to dysfunction of the seminiferous tubules⁸⁸. GPR56 has been shown to be overexpressed in various cancers such as bone, skin, colorectal and prostate^{50,53}.

1.5.4 BAI1 (ADGRB1)

Brain-specific angiogenesis inhibitor 1, BAI1 (ADGRB1), is a member of the B subfamily and binds the endogenous ligands phosphatidylserine and matrix metalloprotease 14^{50,53}. The receptor is expressed in macrophages, astrocytes, microglia, skeletal muscle, heart, central and peripheral neurons, kidneys, and breast^{50,53}. On phagocytes such as macrophages, BAI1 binds phosphatidylserine on apoptotic cells and lipopolysaccharide on gram-negative bacteria to initiate their phagocytosis^{89,90}. In skeletal muscle, BAI1 promotes the fusion of myoblasts into muscle fibers⁹¹. In the brain, BAI1

expression levels have been shown to regulate synaptogenesis⁹². As the name suggests BAI1 inhibits angiogenesis, therefore it is not surprising this receptor is downregulated in various cancers such as brain, lung, breast, colorectal, and renal^{50,53}.

1.6 Tools for studying aGPCR signaling and function

Based on the observation that removal of the N-terminal fragment activates aGPCRs, truncated receptors where only the C-terminal fragment is expressed have been used to study aGPCR signalling^{50,59,61}. These truncated receptors have two main limitations. First, they have low surface expression because they do not have an N-terminal signal sequence. Second, lacking the N-terminal fragment means they are expressed as pre-activated receptors. Therefore, methods of measuring signaling are limited to time independent accumulation assays, such as gene reporter assays. The GPCR field has generally moved away from using gene reporter assays, as they measure downstream signaling outcomes that are prone to crosstalk. Therefore, it is generally preferred to use assays that time dependently show the recruitment of receptor proximal effector proteins. We sought to create a system where we could measure the time dependent recruitment of aGPCR effector proteins and maintain proper surface expression of the receptor. Since removal of the N-terminal fragment is fundamental to the activation of aGPCRs, we reasoned that using an alternative method to remove the N-terminal fragment would also allow study of receptor-effector coupling. Since PAR receptors also signal through proteolytic unmasking of a tethered ligand, we reasoned that a PAR2-aGPCR chimera would enable trypsin mediated cleavage of the receptor N-terminus to trigger signaling through these receptors. *Therefore, we hypothesized that a PAR2-aGPCR chimeric receptors would enable study of receptor-proximal aGPCR signaling events.*

As mentioned above, peptides made to mimic certain lengths of the stalk region have been shown to activate many different aGPCRs. These aGPCRs include: GPR56, GPR110, GPR126 (ADGRG6), GPR133 (ADGRD1), GPR64 (ADGRG2), GPR114 (ADGRG5), GPR116 (ADGRF5) and LPHN1 (ADGRL1)^{59,61,93,94}. However, tethered ligand mimicking peptide has yet to be made for CD97. By analyzing these past studies, we reasoned it was possible to predict the sequence of a CD97 tethered ligand mimicking

peptide. *Therefore, we hypothesized that a peptide made to mimic a certain length of the CD97 stalk region could be used to activate and study receptor signaling.*

The two specific aims of this thesis are to:

1. Create trypsin activated PAR2-CD97, PAR2-EMR2, PAR2-GPR56, and PAR2-BAI1 chimeric receptors as tools to study aGPCR signaling
2. Design and test a tethered ligand mimicking peptide capable of activating CD97.

Chapter 2

2 Methods

2.1 Chemicals and reagents

Unless stated otherwise, all chemicals and reagents were obtained from ThermoFisher Scientific (Hampton, New Hampshire, United States), Millipore-Sigma (Burlington, Massachusetts, United States), or BioShop Canada Inc. (Burlington, Ontario, Canada). Porcine pancreatic trypsin (EC# 3.4.21.4) was purchased from Sigma Aldrich (St. Louis, Michigan, United States). A maximum specific activity of 20 000 units/mg was used to determine trypsin concentrations in molar as previously described⁹⁵ (1unit/mL converts to around 2nM). Trypsin stock solutions were prepared in 25mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) and diluted down to working concentrations in Hanks' balanced salt solution (HBSS). SLIGRL-NH₂ was produced and purchased from Genscript (Piscataway, New Jersey, United States). SSFAILMAH-NH₂ was synthesized using solid phase peptide synthesis at the Luyt Laboratory in Victoria hospital as previously described⁹⁶. SLIGRL-NH₂ was diluted in 25mM HEPES and HBSS, whereas SSFAILMAH-NH₂ was dissolved in 100% dimethylsulfoxide (DMSO). For experiments SSFAILMAH-NH₂ stock solutions were made in 100% DMSO and then diluted to the proper assay condition concentrations using HBSS pre-warmed to 37°C. Therefore, each concentration of SSFAILMAH-NH₂ contained the same amount of DMSO (6%). SSFAILMAH-NH₂ diluted in less than 6% DMSO precipitated out of solution. Vehicle control for all SSFAILMAH-NH₂ assays consisted of HBSS with 6% DMSO. These higher concentrations of DMSO are required for aGPCR tethered ligand mimicking peptides, such as SSFAILMAH-NH₂, due to their highly hydrophobic nature⁵⁹.

2.2 Molecular cloning and constructs

PAR2-adhesion GPCR chimeric receptors for CD97, EMR2, GPR56, and BAI1 were designed using the program Benchling (<https://benchling.com>) (San Francisco, California, United States) and sequence verified synthetic genes were obtained (Integrated DNA Technologies, Coralville, Iowa, United States). PAR2-aGPCR chimeric

receptors were cloned into the pcDNA3.1+ vector (ThermoFisher Scientific, Waltham, MA) using Not1 and Xho1 restriction enzymes (New England Biolabs, Whitby, Ontario, Canada), as previously described^{97,98}. In brief, chimeric receptors in their provided IDT AMP vector (Integrated DNA Technologies, Coralville, Iowa, United States) were incubated overnight at 37°C with Not1 and Xho1 restriction enzymes in NEB 3.1 buffer (New England Biolabs, Whitby, Ontario, Canada). Chimeric receptor inserts were isolated by gel electrophoreses on a 1.5% agarose gel (Sigma Aldrich, St. Louis, Michigan, United States). Chimeric receptor insert DNA was gel purified (Qiagen, Hilden, Germany) and incubated overnight at 16°C with T4 ligase (New England Biolabs, Whitby, Ontario, Canada) and Not1 and Xho1 digested pcDNA3.1+ vector. After ligation, chimeric receptors in pcDNA3.1+ were transformed into max efficiency DH5 α cells (Invitrogen; ThermoFisher Scientific, Waltham, Massachusetts, United States) and grown overnight on 100 μ g/mL ampicillin (BioShop Canada Inc., Burlington, Ontario, Canada) Luria broth (LB) (ThermoFisher Scientific, Hampton, New Hampshire, United States) plates. Single colonies were selected and grown overnight in Terrific broth (TB) (Sigma Aldrich, St. Louis, Michigan, United States) containing 100 μ g/mL ampicillin. Chimeric receptors in pcDNA3.1+ were miniprep (Qiagen, Hilden, Germany) purified and sent for sequencing. Enhanced yellow fluorescent protein (eYFP) (Clontech, Takara Bio, San Jose, CA)⁹⁹ was cloned onto the C-terminus of the PAR2-aGPCR chimeric receptors using Xho1 and Xba1 restriction enzymes (New England Biolabs, Whitby, Ontario, Canada), as previously described^{97,98}. In brief, aGPCR chimeric receptors in pcDNA3.1+ were incubated overnight at 37°C with Xho1 and Xba1 restriction enzymes in NEB CutSmart buffer (New England Biolabs, Whitby, Ontario, Canada). Chimeric receptor in pcDNA3.1+ were separated from the DNA fragments between Xho1-Xba1 by gel electrophoreses on a 1.5% agarose gel. Chimeric receptors in pcDNA3.1+ digested with Xho1 and Xba1 were gel purified and incubated overnight at 16°C with T4 ligase and Xho1 and Xba1 digested eYFP. After ligation, eYFP tagged chimeric receptors in pcDNA3.1+ were transformed into max efficiency DH5 α cells and grown overnight on 100 μ g/mL ampicillin LB plates. Single colonies were selected and grown overnight in TB containing 100 μ g/mL ampicillin. eYFP tagged chimeric receptors were miniprep purified and sent for sequencing. Renilla luciferase-tagged β -arrestins 1 and 2 constructs

were a kind gift from Dr. Michel Bouvier (University of Montreal)^{96,100}. Renilla luciferase tagged G α proteins were a kind gift from Dr. Bryan Roth (University of North Carolina, Chapel Hill)¹⁰¹. PAR2 and CD97 TANGO constructs were a kind gift from Dr. Bryan Roth (University of North Carolina, Chapel Hill, NC)¹⁰² and were obtained from Addgene (Watertown, Massachusetts, United States). Sequence verified constructs were transformed into sub cloning efficiency DH5 α cells (Invitrogen; ThermoFisher Scientific, Waltham, Massachusetts, United States) for amplification and grown overnight on 100 μ g/mL ampicillin LB plates. Single colonies were selected and grown overnight in TB containing 100 μ g/mL ampicillin. DNA was first purified using miniprep, and once sequence verified DNA was purified in larger quantities using midiprep (Qiagen, Hilden, Germany). All constructs were verified by Sanger sequencing (London Regional Genomics Centre, University of Western Ontario).

2.3 Cell lines and culturing conditions

All cell culture media and reagents were purchased from ThermoFisher Scientific (Waltham, MA) unless otherwise stated. PAR2 knock out (PAR2-KO) Human Embryonic Kidney 293 cells (HEK293) (ATCC; Manassas, Virginia United States) were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 100 μ g/ μ L penicillin streptomycin, and 1% sodium pyruvate. PAR2-KO HEK293 cells were previously generated using CRISPR/Cas9 targeting¹⁰⁰. In brief, the specific guide RNA CCCCAGCAGCCACGCCGCGC was cloned into the lentiCRISPR v2 vector (Addgene, Watertown, Massachusetts, United States). HEK293 cells were transfected with the specific guide RNA using X-tremegene9 and grown in selection media containing 5 μ g/mL puromycin. Deficiency of PAR2 was determined by calcium signaling assays with PAR2 agonists trypsin and SLIGRL-NH₂¹⁰⁰.

To generate stable cell lines expressing PAR2-aGPCR chimeras PAR2-KO cells were transiently transfected with either PAR2-CD97, PAR2-EMR2, PAR2-GPR56, or PAR2-BAI eYFP tagged chimeric receptors. At 72 hours post transfection cells were switched to antibiotic selection media. The antibiotic selection media consisted of DMEM supplemented with 600 μ g/mL G418 sulfate (Geneticin; ThermoFisher Scientific, Waltham, Massachusetts, United States), 10% fetal bovine serum, 100 μ g/ μ L penicillin

streptomycin, and 1% sodium pyruvate. After 4 weeks of culture in G418 selection media, eYFP expressing cells were selected by flow cytometry (FACS Aria III; London Regional Flow Cytometry Facility).

HTLA cells were a kind gift from Dr. Gilad Barnea (Brown University)¹⁰³. HTLA cells were maintained in DMEM supplemented with 10% fetal bovine serum, 100 μ g/ μ L penicillin streptomycin, 1% sodium pyruvate, 5 μ g/mL puromycin, 200 μ g/mL hygromycin B, and 500 μ g/mL G418 sulfate.

HEK293 cells were maintained in DMEM supplemented with 10% fetal bovine serum, 100 μ g/ μ L penicillin streptomycin, and 1% sodium pyruvate.

Subsequently all cell lines were sub-cultured every 48 hours using enzyme-free isotonic (pH 7.4) phosphate buffered saline (PBS) supplemented with 1mM ethylenediaminetetraacetic acid (EDTA) to detach cells. PBS-EDTA was then removed by centrifugation. Trypsin EDTA was not used for subculturing as it would activate PAR2-aGPCR chimeric receptors, or endogenously expressed PAR receptors which could affect experimental results. Cells were then resuspended with appropriate growth medium and counted using trypan blue and a hemocytometer.

For BRET and TANGO experiments, 700000 cells/well were plated in six well plates and transiently transfected with X-tremegene9 in optimized minimal essential medium (Opti-MEM). After 24 hours post-transfection cells were transferred into 96-well white bottom plates at a seeding density of 35000 cells/well. BRET and TANGO experiments were performed 48 hours post-transfection. For confocal microscopy experiments, 35000 cells were seeded in 35-mm glass bottom culture dishes (MatTek Corporation, Ashland, MA) coated with 0.05mg/ml poly D-lysine and imaged 48 hours after seeding. Each experiment was performed in either duplicate or triplicate a minimum of three times, on three different days, and with three separate transfections (N=3).

2.4 Confocal microscopy

PAR2-KO cells stably expressing either PAR2-CD97, PAR2-EMR2, PAR2-GPR56, or PAR2-BAI1 eYFP tagged chimeric receptors were seeded at a density of 35000 cells and

cultured on 35mm glass bottom dishes for imaging. Before seeding, glass bottom dishes were coated with 0.05mg/ml poly D-lysine. Cells were imaged 48 hours after plating on a Nikon Eclipse Ti2-E spinning disk confocal microscope (Minato City, Tokyo, Japan) at 60x magnification to determine the cellular localization of PAR2-aGPCR chimeric receptors.

2.5 Bioluminescence resonance energy transfer 1 assay for β -arrestin recruitment

The ability of PAR2-aGPCR chimeric receptors to recruit β -arrestins 1 and 2 was assessed using a bioluminescence resonance energy transfer 1 (BRET1) assay (Fig 5 and Fig 6)^{96,104}. The BRET1 assay consists of the BRET pair eYFP and RLuc proteins. The chimeric receptors were C-terminally tagged with eYFP and β -arrestins 1 and 2 were tagged with RLuc. During RLuc catalysis of coelenterazine H to coelenteramide (NanoLight Technology, Pinetop, AZ) light is emitted at the wavelength that can excite eYFP. BRET is dependent on the distance between the donor luciferase and acceptor fluorophore. Upon addition of receptor activating drug, receptor recruitment of β -arrestin brings the eYFP and RLuc tags into close proximity resulting in an energy transfer to eYFP and an increase in fluorescence^{96,104}. Receptor β -arrestin coupling was confirmed if agonist dose dependent changes in the ratio of eYFP fluorescence/RLuc luminescence was observed^{96,104}.

PAR2-KO or HEK293 cells were transfected with either 1 μ g of eYFP tagged PAR2-CD97, PAR2-EMR2, PAR2-GPR56, or PAR2-BAI1 chimeric receptors and 100ng of β -arrestin-RLuc 1 or 2 using a 3:1 ratio of Opti-MEM to X-tremegene9. One day post transfection cells were transferred into a 96-well white plate and seeded at a density of 35000 cells per well. The next day media was aspirated and replaced with 0.3-300nM trypsin or 0.3-300 μ M SSFAILMAH-NH₂. After 10 minutes of drug treatment cells were treated with 5 μ M coelenterazine H. After 20 minutes of drug treatment plates were read using a Berthold Mithras LB 940 plate reader and BRET ratios of eYFP fluorescence/RLuc luminescence were determined. NET BRET was then calculated by subtracting the vehicle control BRET ratio from all other samples. Dose response curves were generated using three parameter log agonist vs response non-linear regression

analysis on Graphpad prism 8 with error bars representing the standard error of the mean (SEM).

Figure 5. Principle of β -arrestin recruitment bioluminescence resonance energy transfer 1 (BRET1) assay for trypsin. The PAR2-aGPCR chimeric receptor of interest is C-terminally tagged with eYFP and β -arrestin 1 and 2 are tagged with RLuc and transiently expressed in PAR2-KO HEK293 cells. Upon the addition of agonist and RLuc substrate coelenterazine H, β -arrestin is recruited to the receptor. The proximity of eYFP to the RLuc mediated catalysis of coelenterazine H to coelenteramide causes an energy transfer to eYFP, creating an increase in fluorescence. If a ligand recruits β -arrestin to the receptor there should be dose dependent changes in the BRET ratio of eYFP fluorescence/RLuc luminescence. Figures were generated using the program Biorender (<https://biorender.com>).

Figure 6. Principle of β -arrestin recruitment bioluminescence resonance energy transfer 1 (BRET1) assay for peptides. The PAR2-CD97 chimeric receptor is C-terminally tagged with eYFP and β -arrestin 1 and 2 are tagged with RLuc and transiently expressed in HEK293 cells. Upon the addition of agonist and RLuc substrate coelenterazine H, β -arrestin is recruited to the receptor. The proximity of eYFP to the RLuc mediated catalysis of coelenterazine H to coelenteramide causes an energy transfer to eYFP, creating an increase in fluorescence. If a ligand recruits β -arrestin to the receptor there should be dose dependent changes in the BRET ratio of eYFP fluorescence/RLuc luminescence. Figures were generated using the program Biorender (<https://biorender.com>).

2.6 Bioluminescence resonance energy transfer 1 assay for G-protein recruitment

The ability of PAR2-aGPCR chimeric receptors to recruit various G_{α} proteins was assessed using a bioluminescence resonance energy transfer 1 (BRET1) assay (Fig 7)^{104,105}. The chimeric receptors were C-terminally tagged with eYFP and $G_{sS(short)}$, $G_{sL(Long)}$, G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{gustducin}$, G_q , G_{11} , G_{15} , G_{12} and G_{13} α subunits tagged with RLuc were adapted from the TRUPATH biosensor platform¹⁰¹. Upon addition of drug and RLuc substrate coelenterazine H, if the receptor recruits the G-protein of interest, the close proximity of eYFP to the RLuc mediated catalysis of coelenterazine H to coelenteramide causes an energy transfer to eYFP, creating an increase in fluorescence^{104,105}. Receptor G-protein coupling was confirmed if dose dependent changes in the ratio of eYFP fluorescence/RLuc luminescence was observed^{104,105}. PAR2-KO cells were transfected with 1 μ g of eYFP tagged PAR2-CD97, PAR2-EMR2, PAR2-GPR56, or PAR2-BAI1 chimeric receptors and 100ng of the G_{α} -protein of interest using a 3:1 ratio of Opti-MEM to X-tremegene9. One day post transfection cells were transferred into a 96-well white plate and seeded at a density of 35 000 cells per well. The next day media was aspirated and replaced with 5 μ M coelenterazine H diluted in HBSS and incubated at 37°C for 5 minutes. After 5 minutes of incubation with coelenterazine H cells were treated with 0.3-300nM trypsin and plates were immediately read using a Berthold Mithras LB 940 plate reader and BRET ratios of eYFP fluorescence/RLuc luminescence were determined. NET BRET was then calculated by subtracting the lowest recorded BRET ratio from all samples. All points before the lowest recorded BRET ratio were excluded. Dose response curves were generated using three parameter log agonist vs response non-linear regression analysis on Graphpad prism 8 and error bars represent SEM.

Figure 7. Principle of G-protein recruitment bioluminescence resonance energy transfer 1 (BRET1) assay for trypsin. The PAR2-aGPCR chimeric receptor of interest is C-terminally tagged with eYFP and the G_{α} subunit of interest is tagged with RLuc and transiently expressed in PAR2 KO HEK293 cells. Upon the addition of agonist and RLuc substrate coelenterazine H, the G_{α} subunit of interest is recruited to the receptor. The proximity of eYFP to the RLuc mediated catalysis of coelenterazine H to coelenteramide causes an energy transfer to eYFP, creating an increase in fluorescence. If a ligand recruits the G_{α} subunit of interest to the receptor there should be dose dependent changes in the BRET ratio of eYFP fluorescence/RLuc luminescence. Figures were generated using the program Biorender (<https://biorender.com>).

2.7 TANGO assay

The TANGO assay quantifies receptor activation by measuring the recruitment of β -arrestin 2 (Fig 8)^{102,103,106}. β -arrestins are proteins involved in the desensitization of GPCRs and are preferentially recruited to activated receptors^{29,30,33,34}. The assay requires HTLA cells and transfection with a TANGO receptor construct^{102,103,106}. HTLA cells are HEK293 cells which express β -arrestin 2 tagged with the TEV protease and a firefly luciferase reporter gene under the control of the tTA transcription factor^{102,103,106}. A TANGO receptor construct has the receptor of interest C-terminally fused at a TEV cleavage site to the tTA transcription factor^{102,103,106}. If the ligand of interest is able to activate the receptor, β -arrestin 2 will be recruited^{102,103,106}. When in close proximity to the receptor the TEV protease will allow tTA to be released and increase the expression of the luciferase receptor gene^{102,103,106}. By treating cells with the luciferase substrate D-luciferin, changes in luminescence can be measured^{102,103,106}. Cells were transfected with 1 μ g of the PAR2 or CD97 TANGO construct using a 3:1 ratio of Opti-MEM to Xtremegene9. One day post transfection cells were lifted in serum free media and seeded into a 96-well white plate at a density of 35 000 cells per well. Peptide agonists SLIGRL-NH₂ and SSFAILMAH-NH₂ were then added in concentrations ranging from 0.3-300 μ M and incubated with cells for 24 hours. After 24 hours of drug treatment, drug and media were carefully aspirated and replaced with Glo reagent. Glo reagent consisted of 0.14 mg/mL D-luciferin, 1.1mM ATP, 2.5% v/v Triton-x100, 5mM dichloro-diphenyl-trichloroethane (DDT), 75mM NaCl, 3mM MgCl, 108mM Tris-HCl, 42mM Tris-Base, and HBSS^{102,106}. After 20 minutes of incubation with Glo reagent plates were read using a Berthold Mithras LB 940 plate reader and luminescence values were recorded. Luminescence values were normalized, with the HBSS blank set at 0% and the highest recorded luminescence set at 100%. Dose response curves were generated using three parameter log agonist vs response non-linear regression analysis on Graphpad prism 8 and error bars represent SEM.

Figure 8. Principle of the TANGO assay. The receptor is C-terminally fused at a TEV protease cleavage site to the tTA transcription factor and transiently expressed in HLTA cells. HLTA cells are HEK293 cells which express β -arrestin 2 tagged with the TEV protease and a firefly luciferase reporter gene under the control of the tTA transcription factor. If the ligand tested is able to activate the receptor, β -arrestin is recruited to the receptor. This allows TEV to cleave tTA free of the receptor, where it translocates to the nucleus and increases the expression of the luciferase reporter gene. Figures were generated using the program Biorender (<https://biorender.com>).

Chapter 3

3 Results and discussion

3.1 Results

3.1.1 PAR2-aGPCR chimeric receptor design

As mentioned in chapter 1 PARs are also activated by a tethered agonist, but instead of mechanical forces, the PAR tethered agonist is revealed by proteolytic cleavage of the receptor N-terminus⁴⁸. As removal of the aGPCR N-terminal fragment has been shown to be important for receptor activation⁴⁶, we reasoned that replacing the N-terminal fragment of aGPCRs with the N-terminus of a PAR receptor would enable proteolytic unmasking of the aGPCR C-terminal fragment. To enable protease cleavage at a specific site, recognition sites for different proteases can be engineered into proteins¹⁰⁷. Depending on the protease used, introduction of these tags can leave an exogenous residue on the protein of interest after cleavage¹⁰⁷. Since the sequence of the revealed C-terminal fragment is critical for activation of signaling we wanted to establish a method that did not result in any changes to the revealed aGPCR sequence. PARs can be N-terminally cleaved by thrombin and trypsin, with PAR1 being the high affinity thrombin receptor and PAR2 being the high affinity trypsin receptor⁴⁸. Therefore, we examined thrombin and trypsin cleavage site specificities to determine which PAR receptor N-terminus could be fused to the C-terminal fragments of aGPCRs to produce cleavage sites which leave no exogenous sequence behind.

3.1.1.1 Thrombin PAR1-aGPCR chimeric receptor approach

We first examined the cleavage specificity of the PAR1 agonist thrombin. The canonical thrombin cleavage site for PAR1 is between residues R41 and S42⁴⁸. Fluorescence-based cleavage assays studying thrombin P1, P1', and P2' cleavage site specificities revealed that for high affinity thrombin cleavage P1 must be R, P1' must be S, and P2' must be F¹⁰⁸. Protease cleavage sites P1, P1', and P2' are described using the Schechter and Berger nomenclature¹⁰⁹. Therefore, in our system P1 would be the last residue of the PAR1 N-terminus, R41, and P1' and P2' would be the first two residues of the aGPCR C-

terminal fragment. By aligning the stalk regions for all 33 aGPCRs using the GPCRdb alignment tool (<https://gpcrdb.org>) (Fig 9) we found that only 9/33 aGPCRs have P1'=S, only 1/33 have P2'=F, and 0/33 have both P1'=S and P2'=F. Therefore, the PAR1 N-terminus cannot be fused to any aGPCR C-terminal fragment to create thrombin activated receptors without changing the sequence of aGPCR C-terminal fragments. Recently a group of researchers made a thrombin activated PAR1-LPHN3 (ADGRL3) chimeric receptor¹¹⁰. To achieve sufficient thrombin cleavage, they had to change the first residue of the LPHN3 stalk region from T to S and put in a frame shift mutation by deleting the second residue, N¹¹⁰. This therefore created the thrombin cleavage site P1=R, P1'=S, and P2'=F for their PAR1-LPHN3 chimeric receptor¹¹⁰. Although these researchers claim their approach can be more broadly applied to study other aGPCRs¹¹⁰, this approach will only work if the first two residues of the aGPCR C-terminal fragment are changed to P1'=S and P2'=F. As the downstream signaling of many aGPCRs has yet to be determined, and it is known that changes to individual amino acids in the tethered ligand can influence signaling outcomes⁵⁹, it is not ideal to change the first two residues of this highly conserved sequence when studying aGPCR signaling. A second major limitation of this study relates to the endogenous expression of the thrombin activated GPCR PAR1 in the cell lines used to study the chimeric PAR1-LPHN3 receptor¹¹⁰. The methods used to study signaling measured the interaction of G proteins with downstream effectors, and not the direct interaction of G proteins with the receptor¹¹⁰. As PAR1 is endogenously expressed in HEK293 cells it is possible they were simply measuring the thrombin mediated response of the canonical thrombin receptor, PAR1.

Figure 9. Alignment of all 33 adhesion GPCRs stalk regions. The stalk region corresponds to the beginning of the C-terminal fragment to the first transmembrane domain. Highlighted in yellow is the β -13 strand, which creates the key non-covalent interactions holding the receptor together and also appears to contain the tethered agonistic for adhesion GPCRs. Highlighted in blue are predicted turn elements, which seemed to be required in tethered ligand mimicking peptides for proper activity. The majority of adhesion GPCRs stalk regions begin with either a S or T residue (highlighted in red), allowing the creation of a trypsin cleavage site when fused to the first 36 amino acids of PAR2. Alignment of all 33 aGPCR stalk regions was done using the GPCRdb alignment tool (<https://gpcrdb.org>).

3.1.1.2 Trypsin PAR2-aGPCR chimeric receptor approach

As the PAR1 thrombin activated approach would require substantial changes and optimization for each aGPCR chimeric receptor, we next examined the cleavage specificity of the PAR2 agonist trypsin. The canonical trypsin cleavage site for PAR2 is between residues R36 and S37⁴⁸. Referring back to our alignment of the 33 aGPCR stalk regions we found that the C-terminal fragments of 27/33 aGPCRs begin with either a S or T residue (Fig 9). Another fluorescence-based cleavage assay which looked at trypsin P1' and P2' residue specificity determined that trypsin cleaves all of the 19 possible P2' residues as long as P1=R and P1'=S¹¹¹. They also found that trypsin cleaves 12/19 possible P2' residues as long as P1=R and P1'=T¹¹¹. Therefore, 26/27 of the aGPCRs that have stalk regions beginning with either S or T can be made into trypsin activated receptors without any changes to the receptors C-terminal fragment. This can be done by fusing the first 36 amino acids of PAR2, ending in R36, with the C-terminal fragment of an aGPCR beginning with S37 or T37. Further, 2/6 aGPCR stalk regions that do not begin with S or T can still form trypsin cleavage sites when fused to the PAR2 N-terminus. Therefore, our PAR2-aGPCR chimeric receptor approach can be used to make trypsin activated receptors for 29/33 aGPCRs without making any changes to the receptors C-terminal fragment. Upon the addition of trypsin, the PAR2 N-terminus would be removed and the aGPCR C-terminal fragment would be exposed via a mechanism that is almost identical to the canonical PAR activation mechanism (Fig 10). These chimeric receptors could then be time dependently activated with nM concentrations of trypsin to study aGPCR signaling. As mentioned in chapter 1 a limitation of the truncated receptor method is that they show low cell surface expression because they lack an N-terminal signal sequence. However, our PAR2-aGPCR chimeric receptors should show normal cell surface expression as they contain the PAR2 N-terminal signal sequence¹¹². Further, to ensure we were measuring the response of the aGPCR of interest and not endogenously expressed PARs, all our signaling experiments measured the direct interaction of the chimeric receptor with effector proteins and were done in PAR2-KO cells that are devoid of the trypsin responsive receptor PAR2.

Figure 10. Illustration of our PAR2-aGPCR chimeric receptor design. The first 36 amino acids of PAR2 are fused to the C-terminal fragment of the aGPCR of interest. Upon the addition of nM concentrations of trypsin, the PAR2 N-terminus is removed allowing either the tethered agonist or conformational change to activate the receptor. Figures were generated using the program Biorender (<https://biorender.com>).

3.1.2 PAR2-CD97, PAR2-EMR2, PAR2-GPR56, PAR2-BAI1 chimeric receptors

As mentioned in chapter 1, we chose to study CD97, EMR2, GPR56, and BAI1 because they are 4 of the more well studied aGPCRs, and all have significant relevance in normal physiology and disease. Further, these receptors are representative members of 3 aGPCR subfamilies. The PAR2-CD97 chimeric receptor has a trypsin cleavage site of P1=R, P1'=S, and P2'=S. The PAR2-EMR2 chimeric receptor has a trypsin cleavage site of P1=R, P1'=S, and P2'=S. The PAR2-GPR56 chimeric receptor has a trypsin cleavage site of P1=R, P1'=T, and P2'=Y. The PAR2-BAI1 chimeric receptor has a trypsin cleavage site of P1=R, P1'=S, and P2'=T. Therefore 3 of our 4 chimeric receptors have unique trypsin cleavage sites (Fig 11), which supports the wide applicability of our approach to the receptor family as a whole.

Figure 11. Illustrations of protease cleavage specificities and PAR2-aGPCR chimeric receptor cleavage sites. A) Thrombin cleavage specificity. Thrombin requires P1=R, P1'=S, and P2'=F for high affinity cleavage. B) Trypsin cleavage site specificity. Trypsin will cleave any of the possible P2' residues as long as P1=R and P1'=S. Trypsin will also cleave 12/19 of the possible P2' residues as long as P1=R and P1'=T. C) PAR2-CD97 chimeric receptor design. The first 36 amino acids of PAR2 ending in R36 were fused to the C-terminal fragment of CD97, with P1=R, P1'=S, and P2'=S. D) PAR2-EMR2 chimeric receptor design. The first 36 amino acids of PAR2 ending in R36 were fused to the C-terminal fragment of EMR2, with P1=R, P1'=S, and P2'=S. E) PAR2-GPR56 chimeric receptor design. The first 36 amino acids of PAR2 ending in R36 were fused to the C-terminal fragment of GPR56, with P1=R, P1'=T, and P2'=Y. F) PAR2-BAI1 chimeric receptor design. The first 36 amino acids of PAR2 ending in R36 were fused to the C-terminal fragment of BAI1, with P1=R, P1'=S, and P2'=T. Figures were generated using the program Biorender (<https://biorender.com>).

3.1.3 aGPCR chimeric receptor expression

PAR2-KO cells stably expressing either PAR2-CD97, PAR2-EMR2, PAR2-GPR56, or PAR2-BAI1 eYFP tagged chimeric receptors were analyzed by confocal microscopy to determine their cellular localization (Fig 12). PAR2-CD97, PAR2-EMR2, and PAR2-BAI1 chimeric receptors all appeared to be expressed on the cell membrane. However, the PAR2-GPR56 chimeric receptor appeared to be mainly expressed inside the cell.

Figure 12. PAR2-aGPCR chimeric receptor expression in PAR2-KO stable cells (N=3). PAR2-KO cells stably expressed eYFP tagged PAR2-CD97, EMR2, GPR56, and BA11 chimeric receptors were cultured on 35mm glass bottom dishes for imaging. Cells were imaged on a Nikon spinning disk confocal microscope at 60x magnification to determine cellular localization of PAR2-aGPCR chimeric receptors.

3.1.4 CD97 β -arrestin and G-protein recruitment profile

BRET1 assays with eYFP tagged PAR2-CD97 chimeric receptor as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{gustducin}$, $G_{sS(short)}$, $G_{sL(Long)}$) effectors as the photon donor were done to determine the effector coupling profile of CD97 (Fig 13). When treated with increasing concentrations of trypsin CD97 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for both β -arrestin 1 ($EC_{50}=61.59nM$) and 2 ($EC_{50}=136.5nM$). When treated with increasing concentrations of trypsin CD97 also caused dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for G_{12} ($EC_{50}=48.85nM$), G_{13} ($EC_{50}=169.1nM$), G_q ($EC_{50}=78.83nM$), G_{11} ($EC_{50}=87.10nM$), G_{15} ($EC_{50}=1092nM$), G_{i1} ($EC_{50}=65.73nM$), G_{i2} ($EC_{50}=23.10nM$), G_{i3} ($EC_{50}=91.31nM$), G_{oA} ($EC_{50}=110.6nM$), G_{oB} ($EC_{50}=80.90nM$), G_z ($EC_{50}=67.27nM$), $G_{gustducin}$ ($EC_{50}=155.5nM$), $G_{sL(Long)}$ ($EC_{50}=250.0nM$), and $G_{sS(short)}$ ($EC_{50}=568.8nM$).

Figure 13. β -arrestin and G-protein recruitment profile of CD97 (N=3-5). Bioluminescence resonance energy transfer 1 (BRET1) assays where the PAR2-CD97 chimeric receptor tagged with eYFP acted as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{\text{gustducin}}$, $G_{sS(\text{short})}$, $G_{sL(\text{Long})}$) effectors acted as the photon donor. For β -arrestin recruitment assays PAR2-CD97 chimeric receptors were transiently expressed in PAR2-KO HEK293 cells and treated for 20 minutes with 0.3-300nM trypsin. CD97 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for both β -arrestin 1 ($EC_{50}=61.59\text{nM}$) and 2 ($EC_{50}=136.5\text{nM}$). For G-protein recruitment assays PAR2-CD97 chimeric receptors were transiently expressed in PAR2-KO HEK293 cells and treated with 0.3-300nM trypsin. CD97 was also able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for G_{12} ($EC_{50}=48.85\text{nM}$), G_{13} ($EC_{50}=169.1\text{nM}$), G_q ($EC_{50}=78.83\text{nM}$), G_{11}

(EC₅₀=87.10nM), G₁₅ (EC₅₀=1092nM), G_{i1} (EC₅₀=65.73nM), G_{i2} (EC₅₀=23.10nM), G_{i3} (EC₅₀=91.31nM), G_{oA} (EC₅₀=110.6nM), G_{oB} (EC₅₀=80.90nM), G_z (EC₅₀=67.27nM), G_{gustducin} (EC₅₀=155.5nM), G_{sL(Long)} (EC₅₀=250.0nM), and G_{sS(short)} (EC₅₀=568.8nM).

3.1.5 EMR2 β -arrestin and G-protein recruitment profile

BRET1 assays with eYFP tagged PAR2-EMR2 chimeric receptor as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{gustducin}$, $G_{sS(short)}$, $G_{sL(Long)}$) effectors as the photon donor were done to determine the effector coupling profile of EMR2 (Fig 14). When treated with increasing concentrations of trypsin EMR2 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for both β -arrestin 1 ($EC_{50}=44.35nM$) and 2 ($EC_{50}=28.90nM$). When treated with increasing concentrations of trypsin EMR2 was also able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for G_{12} ($EC_{50}=92.01nM$), G_{13} ($EC_{50}=162.8nM$), G_q ($EC_{50}=209.8nM$), G_{11} ($EC_{50}=95.71nM$), G_{15} ($EC_{50}=185.4nM$), G_{i1} ($EC_{50}=79.28nM$), G_{i2} ($EC_{50}=115.4nM$), G_{i3} ($EC_{50}=123.9nM$), G_{oA} ($EC_{50}=75.90nM$), G_{oB} ($EC_{50}=144.9nM$), G_z ($EC_{50}=249.5nM$), $G_{gustducin}$ ($EC_{50}=100.9nM$), $G_{sL(Long)}$ ($EC_{50}=155.6nM$), and $G_{sS(short)}$ ($EC_{50}=74.45nM$).

Figure 14. β -arrestin and G-protein recruitment profile of EMR2 (N=3-5).

Bioluminescence resonance energy transfer 1 (BRET1) assays where the PAR2-EMR2 chimeric receptor tagged with eYFP acted as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , G_{gust} ducin, G_{sS} (short), G_{sL} (Long)) effectors acted as the photon donor. For β -arrestin recruitment assays PAR2-EMR2 chimeric receptors were transiently expressed in PAR2 KO HEK293 cells and treated for 20 minutes with 0.3-300nM trypsin. EMR2 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence both β -arrestin 1 (EC_{50} =44.35nM) and 2 (EC_{50} =28.90nM). For G-protein recruitment assays PAR2-EMR2 chimeric receptors were transiently expressed in PAR2-KO HEK293 cells and treated with 0.3-300nM trypsin. EMR2 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for G_{12} (EC_{50} =92.01nM), G_{13} (EC_{50} =162.8nM), G_q (EC_{50} =209.8nM), G_{11} (EC_{50} =95.71nM), G_{15}

(EC₅₀=185.4nM), G_{i1} (EC₅₀=79.28nM), G_{i2} (EC₅₀=115.4nM), G_{i3} (EC₅₀=123.9nM), G_{oA} (EC₅₀=75.90nM), G_{oB} (EC₅₀=144.9nM), G_z (EC₅₀=249.5nM), G_{gustducin} (EC₅₀=100.9nM), G_{sL(Long)} (EC₅₀=155.6nM), and G_{sS(short)} (EC₅₀=74.45nM).

3.1.6 GPR56 β -arrestin and G-protein recruitment profile

BRET1 assays with eYFP tagged PAR2-GPR56 chimeric receptor as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{gustducin}$, $G_{sS(short)}$, $G_{sL(Long)}$) effectors as the photon donor were done to determine the effector coupling profile profile of GPR56 (Fig 15). When treated with increasing concentrations of trypsin GPR56 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for both β -arrestin 1 ($EC_{50}=25.00nM$) and 2 ($EC_{50}=24.41nM$). When treated with increasing concentrations of trypsin GPR56 was also able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for G_{12} ($EC_{50}=59.14nM$), G_{13} ($EC_{50}=78.16nM$), G_q ($EC_{50}=85.33nM$), G_{11} ($EC_{50}=65.99nM$), G_{15} ($EC_{50}=17.79nM$), G_{i1} ($EC_{50}=148.5nM$), G_{i2} ($EC_{50}=841.5nM$), G_{i3} ($EC_{50}=151.5nM$), G_{oA} ($EC_{50}=47.23nM$), G_{oB} ($EC_{50}=69.99nM$), G_z ($EC_{50}=892.0nM$), $G_{gustducin}$ ($EC_{50}=702.3nM$), $G_{sL(Long)}$ ($EC_{50}=52.52nM$), and $G_{sS(short)}$ ($EC_{50}=49.84nM$).

Figure 15. β -arrestin and G-protein recruitment profile of GPR56 (N=3-5).

Bioluminescence resonance energy transfer 1 (BRET1) assays where the PAR2-GPR56 chimeric receptor tagged with eYFP acted as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , G_{gust} ducin, G_{sS} (short), G_{sL} (Long)) effectors acted as the photon donor. For β -arrestin recruitment assays PAR2-GPR56 chimeric receptors were transiently expressed in PAR2 KO HEK293 cells and treated for 20 minutes with 0.3-300nM trypsin. GPR56 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for both β -arrestin 1 (EC_{50} =25.00nM) and 2 (EC_{50} =24.41nM). For G-protein recruitment assays PAR2-GPR56 chimeric receptors were transiently expressed in PAR2-KO HEK293 cells and treated with 0.3-300nM trypsin. GPR56 was also able to cause dose-dependent increases in the BRET ratio of

eYFP fluorescence/RLuc luminescence for G₁₂ (EC₅₀=59.14nM), G₁₃ (EC₅₀=78.16nM), G_q (EC₅₀=85.33nM), G₁₁ (EC₅₀=65.99nM), G₁₅ (EC₅₀=17.79nM), G_{i1} (EC₅₀=148.5nM), G_{i2} (EC₅₀=841.5nM), G_{i3} (EC₅₀=151.5nM), G_{oA} (EC₅₀=47.23nM), G_{oB} (EC₅₀=69.99nM), G_z (EC₅₀=892.0nM), G_{gustducin} (EC₅₀=702.3nM), G_{sL(Long)} (EC₅₀=52.52nM), and G_{sS(short)} (EC₅₀=49.84nM).

3.1.7 BAI1 β -arrestin and G-protein recruitment profile

BRET1 assays with eYFP tagged PAR2-BAI1 chimeric receptor as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{gustducin}$, $G_{sS(short)}$, $G_{sL(Long)}$) effectors as the photon donor were done to determine the effector coupling of BAI1 (Fig 16). When treated with increasing concentrations of trypsin BAI1 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for both β -arrestin 1 ($EC_{50}=37.42nM$) and 2 ($EC_{50}=25.72nM$). When treated with increasing concentrations of trypsin BAI1 was also able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for G_{12} ($EC_{50}=73.79nM$), G_{13} ($EC_{50}=39.60nM$), G_q ($EC_{50}=179.4nM$), G_{11} ($EC_{50}=50.66nM$), G_{15} ($EC_{50}=164.3nM$), G_{i1} ($EC_{50}=44.33nM$), G_{i2} ($EC_{50}=82.13nM$), G_{i3} ($EC_{50}=48.37nM$), G_{oA} ($EC_{50}=33.26nM$), G_{oB} ($EC_{50}=47.93nM$), G_z ($EC_{50}=91.97nM$), $G_{gustducin}$ ($EC_{50}=109.5nM$), $G_{sL(Long)}$ ($EC_{50}=178.2nM$), and $G_{sS(short)}$ ($EC_{50}=83.11nM$).

Figure 16. β -arrestin and G-protein recruitment profile of BAI1 (N=3-5).

Bioluminescence resonance energy transfer 1 (BRET1) assays where the PAR2-BAI1 chimeric receptor tagged with eYFP acted as the photon acceptor and 16 different RLuc tagged β -arrestin (β -arrestin 1 and 2) and G-protein (G_{12} , G_{13} , G_q , G_{11} , G_{15} , G_{i1} , G_{i2} , G_{i3} , G_{oA} , G_{oB} , G_z , $G_{gustducin}$, G_{sS} (short), G_{sL} (Long)) effectors acted as the photon donor. For β -arrestin recruitment assays PAR2-BAI1 chimeric receptors were transiently expressed in PAR2 KO HEK293 cells and treated for 20 minutes with 0.3-300nM trypsin. BAI1 was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for both β -arrestin 1 ($EC_{50}=37.42$ nM) and 2 ($EC_{50}=25.72$ nM). For G-protein recruitment assays PAR2-BAI1 chimeric receptors were transiently expressed in PAR2-KO HEK293 cells and treated with 0.3-300nM trypsin. BAI1 was also able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for G_{12} ($EC_{50}=73.79$ nM), G_{13} ($EC_{50}=39.60$ nM), G_q ($EC_{50}=179.4$ nM), G_{11}

(EC₅₀=50.66nM), G₁₅ (EC₅₀=164.3nM), G_{i1} (EC₅₀=44.33nM), G_{i2} (EC₅₀=82.13nM), G_{i3} (EC₅₀=48.37nM), G_{oA} (EC₅₀=33.26nM), G_{oB} (EC₅₀=47.93nM), G_z (EC₅₀=91.97nM), G_{gustducin} (EC₅₀=109.5nM), G_{sL(Long)} (EC₅₀=178.2nM), and G_{sS(short)} (EC₅₀=83.11nM).

3.1.8 Predicting the sequence of a CD97 tethered ligand mimicking peptide

Synthetic peptides made to mimic a receptors tethered ligand can be used to activate the receptor without the need to expose the receptors tethered ligand, as shown in Figure 6. These tethered ligand mimicking peptides are useful tools when studying receptors activated by the same agonist. For example, both PAR1 and PAR4 are activated by thrombin⁴⁸. Therefore, when studying PAR signaling in platelets, which express both PAR1 and PAR4¹¹³, receptor specific tethered ligand mimicking peptides TFLLR-NH₂ for PAR1, and AYPGKF-NH₂ for PAR4, can be used⁴⁸. These tethered ligand mimicking peptides have a similar utility when studying aGPCRs, which are all activated by the same mechanism, mechanical force^{46,50}. Tethered ligand mimicking peptides have currently been determined for 8 of the 33 aGPCRs^{59-61,93,94}. Analyzing these studies gave us valuable insight on how we might generate a peptide that would activate CD97, without having to make peptide library against the CD97 stalk region. The length of agonistic peptides differs greatly between aGPCRs^{59-61,93,94}. For example, GPR56 was found to be activated by a peptide corresponding to the first 7 amino acids of its stalk region⁵⁹. GPR110, on the other hand, was activated by peptides corresponding to the first 9-18 amino acids of its stalk region, with the peptide of 12 amino acids found to be the most potent⁵⁹. It was therefore hypothesized that if the stalk region contains a turn element, then this must be included in the peptide for it to be agonistic⁴⁶. Similar to GPR56, CD97 does not contain any turn elements in its stalk region (Fig 9); therefore, we predicted a shorter peptide would be agonistic. Recent structures of aGPCR N-terminal fragments have shown that the β -13 strand, corresponding to the first 9 amino acids of the aGPCR stalk region, is responsible for making the key non-covalent interactions holding the N-terminal and C-terminal fragments together¹¹⁴. These 9 amino acids show high sequence conservation across aGPCRs (Fig 9), and 7 of the 8 agonistic aGPCR peptides contain all 9 of these amino acids^{59-61,93,94}. Therefore, we generated a peptide corresponding to the first 9 amino acids of the CD97 stalk region, SSFAILMAH-NH₂, and tested its ability to activate the receptor.

3.1.9 Testing the ability of SSFAILMAH-NH₂ to activate CD97

Although TANGO plasmids have been made for over 300 GPCRs, many have not been tested with known receptor agonists¹⁰². To verify that the TANGO assay was a good method for testing tethered ligand mimicking peptides we used the well documented PAR2 tethered ligand mimicking peptide SLIGRL-NH₂ and tested its ability to activate PAR2 using the TANGO assay. SLIGRL-NH₂ was able to cause dose-dependent increases in luminescence ($EC_{50}=10.67\mu\text{M}$) with a similar EC_{50} for β -arrestin 2 as we have previously reported ($EC_{50}=11.1\mu\text{M}$)¹⁰⁰ (Fig 17). We next tested the ability of SSFAILMAH-NH₂ to activate CD97 using the TANGO assay. SSFAILMAH-NH₂ was able to cause dose-dependent increases in luminescence with an EC_{50} of $17.28\mu\text{M}$ (Fig 17). Next, we used a BRET1 assay with eYFP tagged PAR2-CD97 chimeric receptor as the photon acceptor and RLuc tagged β -arrestin 1 and 2 as the photon donors to test the ability of SSFAILMAH-NH₂ to activate CD97. SSFAILMAH-NH₂ was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLuc luminescence for β -arrestin 1 ($EC_{50}=22.86\mu\text{M}$) and 2 ($EC_{50}=78.29\mu\text{M}$) (Fig 17).

Figure 17. TANGO and BRET assays testing the ability of tethered ligand mimicking peptide SSFAILMAH-NH₂ to activate CD97 (N=3). HTLA cells were transiently transfected with PAR2 or CD97 TANGO constructs and treated with 0.3-300μM PAR2 activating peptide SLIGRL-NH₂ or CD97 activating peptide SSFAILMAH-NH₂. A) SLIGRL-NH₂ was able to cause dose-dependent increases in luminescence ($EC_{50}=10.67\mu\text{M}$) with a similar EC_{50} for β-arrestin 2 as we have previously reported ($EC_{50}=11.1\mu\text{M}$)¹⁰⁰. B) SSFAILMAH-NH₂ was able to cause dose-dependent increases in luminescence with an EC_{50} of 17.28μM. Shown on the bottom graphs are BRET1 assays with eYFP tagged PAR2-CD97 chimeric receptor as the photon acceptor and RLUC tagged β-arrestin 1 and 2 as the photon donors to test the ability of

SSFAILMAH-NH₂ to activate CD97. C) and D) SSFAILMAH-NH₂ was able to cause dose-dependent increases in the BRET ratio of eYFP fluorescence/RLUC luminescence for β -arrestin 1 ($EC_{50}=22.86\mu\text{M}$) and 2 ($EC_{50}=78.29\mu\text{M}$).

3.2 Discussion

3.2.1 PAR2-aGPCR chimeric receptor expression

When examined by confocal microscopy our eYFP tagged PAR2-CD97, EMR2, and BAI1 chimeric receptors showed proper cell surface expression (Fig 12). This confirmed that addition of the PAR2 N-terminus allowed proper expression of the receptors and did not result in a constitutively activated receptor that was entirely intracellular as was seen with the truncated receptor method previously used⁶². CD97 showed some intracellular pools of receptor that may reflect a certain level of constitutive activity in this receptor or may be indicative of intracellular pools of this receptor being present in cells to enable rapid repopulation following activation and internalization of cell surface receptors. Such intracellular pools of PAR1 are seen in some cells^{115,116}. The expression pattern of the PAR2-GPR56 chimeric receptor is quite puzzling and this receptor appeared to be expressed almost entirely inside the cell (Fig 12). This is odd since the PAR2-GPR56 chimeric receptor dose dependently recruited a variety of effector proteins (Fig 15). It is possible that the observed localization is the normal sub-cellular expression pattern of GPR56 with only a small population of GPR56 present at the cell membrane and the remaining receptors associated with intracellular protein scaffolds. In future experiments we plan to test this hypothesis by analyzing the expression of full length GPR56. The intracellular structures that our PAR2-GPR56 chimeric receptor is associated with look very similar to mitochondria, and there is evidence that GPR56 is involved with mitochondrial function¹¹⁷. Therefore, in the future we also plan to examine if GPR56 co-localizes with mitochondria markers.

3.2.2 CD97 activation results in the recruitment of β -arrestin and a variety of G-proteins

By creating a chimeric trypsin activated PAR2-CD97 receptor, where the first 36 amino acids of PAR2 were fused to the C-terminal fragment of CD97, we were able to study the recruitment of 16 effector proteins from the 5 major signaling pathways downstream of GPCRs. As shown in figure 13 CD97 dose-dependently recruited both β -arrestin 1 ($EC_{50}=61.59nM$) and 2 ($EC_{50}=136.5nM$). The interaction of CD97 with β -arrestin 1 has been previously shown using co-immunoprecipitation¹¹⁸. In this earlier study CD97 was

overexpressed and co-immunoprecipitation with β -arrestin 1 was compared with cells not overexpressing CD97¹¹⁸. Even though CD97 is not activated, the overexpression of the receptor results in more basal activity compared to cells not overexpressing the receptor. In this study they also identified a site of interaction between CD97 and β -arrestin 1¹¹⁸. Mutation of residues 631 to 641 on intracellular loop 3 (ICL3) and TM6 decreased the interaction of CD97 and β -arrestin 1¹¹⁸. They also determined that GRK6 is involved with phosphorylating CD97 following receptor activation creating binding sites for β -arrestins¹¹⁸. The rather limited approach of overexpressing the full-length inactive receptor to study aGPCR signaling is common because specific synthetic agonists and other methods of activating aGPCRs were not available. Our chimeric receptors have provided another strategy for tackling this problem and we are the first to report the interaction of CD97 with β -arrestin 2, and to show the dose-dependent interaction of CD97 with β -arrestins 1 and 2.

CD97 dose-dependently recruited both G_{12} ($EC_{50}=48.85\text{nM}$) and G_{13} ($EC_{50}=169.1\text{nM}$) (Fig 13). The interaction of CD97 with the $G_{12/13}$ family of G-proteins has been previously documented^{73,119}. Receptors made to express only the C-terminal fragment of CD97 showed higher levels of SRE reporter gene luminescence and RhoA activation compared to full-length receptors. This signaling was shown to be tethered ligand dependent, as receptors truncated to TM1 and therefore lacking the stalk region, did not show any difference in response compared to full length receptors. Although SRE and RhoA are mainly downstream of $G_{12/13}$, these pathways can also be activated by the $G_{q/11}$ family of G-proteins²⁷. This is another example of why the GPCR field is moving away from methods such as gene reporter assays in favor of methods directly measuring the interaction of receptors with effector proteins, as we have done. Recently another study used a yeast cell growth reporter gene assay to show that CD97 interacts with G_{12} and G_{13} ¹¹⁹. In this assay, yeast cell growth is controlled by the $G_{\beta\gamma}$ subunit and all but the G_{α} protein of interest are knocked out¹¹⁹. Therefore, the only way for the yeast cells to grow is if your receptor activates the G-protein of interest¹¹⁹. Yeast cells expressing G_{12} and G_{13} grew more with CD97 receptors lacking the N-terminal fragment than cells expressing full-length receptors, supporting CD97 activation of both G_{12} and G_{13} ¹¹⁹. Our data supports these observations, and we are the first to show the dose-dependent

interaction of CD97 with G_{12/13}. CD97 signaling through G_{12/13} also makes sense as its overexpression in cancer cells increases tumors cell migration and metastasis^{53,55,56,70-74}, a process that is well established to involve G_{12/13} signaling¹²⁰. Also, CD97 has been shown to be expressed at the leading edge of tumors⁵⁶. CD97 G_{12/13} signaling is also likely involved in its role of regulating immune cell migration and mobilization^{50,77-79,121}.

CD97 dose-dependently recruited G_q (EC₅₀=78.83nM) and G₁₁ (EC₅₀=87.10nM) (Fig 13). As the EC₅₀ of G₁₅ recruitment (EC₅₀=1092nM) was very high and response so small and variable we conclude that CD97 likely does not couple to G₁₅. As mentioned in the last paragraph, a G-protein coupling profile for CD97 was recently reported using a yeast cell growth assay¹¹⁹. In this study CD97 was not shown to couple to G₁₆¹¹⁹. As G₁₅ is the mouse homolog of G₁₆, these findings are also in agreement with our data²⁷. Yeast cells expressing G_q and CD97 without its N-terminal fragment grew more than cells expressing full-length receptor¹¹⁹. This supports our data, and we show also that CD97 can dose-dependently recruit G_q and G₁₁. Using the yeast cell growth assay, Bhudia et al also showed that CD97 activated G₁₄. Unfortunately, we did not have a RLuc tagged G₁₄ BRET sensor, therefore future studies will have to be done to support their findings¹⁰¹. As the interaction of CD97 with the G_{q/11} family of G-proteins has only recently been determined, the functional outcome of this signaling in physiology and disease is currently unknown. However, effectors such as Phosphoinositide 3-kinase (PI3K), PLC-β/DAG, and RhoA are downstream of G_{q/11} and are important in immune cell migration and mobilization^{27,121}. Therefore, CD97 G_{q/11} signaling may also contribute to its role in regulating immune cell migration and mobilization²⁵⁻²⁹.

As shown in figure 13 CD97 dose-dependently recruited G_{i1} (EC₅₀=65.73nM), G_{i2} (EC₅₀=23.10nM), G_{i3} (EC₅₀=91.31nM), G_{oA} (EC₅₀=110.6nM), G_{oB} (EC₅₀=80.90nM), G_z (EC₅₀=67.27nM), and G_{gustducin} (EC₅₀=155.5nM). Yeast cells expressing G_{i1} and G_z, but not G_{i3} and G_o, had increased growth when expressed with CD97 without its N-terminal fragment¹¹⁹. Our data supports the coupling of CD97 with G_{i1} and G_z, however we also show dose-dependent coupling to G_{i3}, G_{oA}, and G_{oB}. This discrepancy in results may be explained by the fact that Bhudia et al were using human CD97 with chimeric yeast G-proteins¹¹⁹. The 5 C-terminal amino acids of mammalian G-proteins were added to the

yeast G-protein Gpa1¹¹⁹, since these amino acids are the important mammalian receptor interacting residues. Although this yeast-based assay gave very similar results to our BRET assays in mammalian cells, Bhudia et al do discuss the possibility of false positives and negatives, which could explain our differences in results¹¹⁹. The coupling of CD97 to G_{i1-3} is in keeping with its role in immune cell function. In leukocytes the G_{i1-3} G-proteins are important for regulating many chemokine and chemoattractant responses involved in immune cell activation and recruitment¹²¹. G_{i2} knockout mice develop colitis and colorectal cancer due to an increase in T_H1 type cytokines such as IL-12, which is constitutively repressed by G_{i2} signaling^{27,122,123}. Interestingly, we found that CD97 is a high affinity recruiter of G_{i2} . As discussed in chapter 1 the overexpression of CD97 attenuated experimentally induced colitis⁷¹. Therefore, CD97 signaling through G_{i2} likely reduces inflammatory mediators such as IL-12 associated with the development of colitis. $G_{\beta\gamma}$, which mainly comes from the activation of $G_{i/o}$ G-proteins, can activate PI3K/Protein kinase B (AKT) and inhibit Glycogen synthase kinase 3 β (GSK-3 β) which stabilizes β -catenin for incorporation into adherens junctions^{27,124,125}. CD97 overexpression was shown to protect against colitis by increasing the density of colonic adherens junctions through activation of PI3K/AKT and inhibition of GSK-3 β ⁷¹. CD97 has been shown to bind β -catenin through its PDZ domain¹²⁶. Therefore, the sequestering of β -catenin at the membrane by CD97 may be the result of its G_i mediated stabilization of β -catenin which then binds CD97 to remain membrane localized for incorporation in adherens junctions. By determining the signaling partners of CD97 we may have been able to better explain its function in regulating intestinal barrier permeability. The ability of CD97 to dose dependently recruit G_{oA} , and G_{oB} is surprising as the receptor is not reported to be expressed in neurons or neuroendocrine cells⁵⁰. However, CD97 is involved in glioblastoma, a brain cancer of the neuronal immune cell astrocytes⁵³. Therefore, our results suggest a possible yet undetermined function of CD97 in the CNS. It is not surprising that CD97 is a high affinity recruiter of G_z , as this G-protein is expressed in hematopoietic cells and likely contributes to its function in regulating immune cell responses^{27,28}. The ability of CD97 to dose-dependently recruit $G_{\text{gustducin}}$ is quite interesting. This would suggest a possible role for CD97 in nutrient sensing in the gastrointestinal tract, as the receptor is not known to be expressed in the tongue but is

expressed in the stomach and intestinal absorptive, goblet, Paneth, and enteroendocrine cells^{50,69,127}.

As the EC_{50} of $G_{sL(Long)}$ ($EC_{50}=250.0nM$), and $G_{sS(short)}$ ($EC_{50}=568.8nM$) recruitment by CD97 was quite high and the magnitude of the responses was small and variable we conclude that CD97 likely doesn't couple to the G_s family of G-proteins (Fig 13). Our data is supported by the fact that yeast cells expressing G_s and CD97 without its N-terminal fragment grew no differently than cells expressing full-length receptors¹¹⁹.

3.2.3 EMR2 activation results in the recruitment of β -arrestin and a variety of G-proteins

By creating a chimeric trypsin activated PAR2-EMR2 receptor, where the first 36 amino acids of PAR2 were fused to the C-terminal fragment of EMR2, we were able to study the recruitment of 16 effector proteins from the 5 major signaling pathways downstream of GPCRs. As shown in figure 14 EMR2 dose-dependently recruited both β -arrestin 1 ($EC_{50}=44.35nM$) and 2 ($EC_{50}=28.90nM$). We are the first to show the dose-dependent interaction of EMR2 with β -arrestins.

EMR2 dose-dependently recruited G_{12} ($EC_{50}=92.01nM$) and G_{13} ($EC_{50}=162.8nM$) (Fig 14). Our results are in keeping with studies in yeast cells where expressing $G_{12/13}$ and EMR2 without its N-terminal fragment resulted in more growth than cell expressing full-length receptor¹¹⁹. EMR2 $G_{12/13}$ signaling is likely involved in its role in cell migration and metastasis in various cancers⁵³. $G_{12/13}$ signaling is also likely involved in its role in neutrophil migration, degranulation, and cytokine secretion^{50,80,81}.

As shown in figure 14 EMR2 dose-dependently recruited G_q ($EC_{50}=209.8nM$), G_{11} ($EC_{50}=95.71nM$) and G_{15} ($EC_{50}=185.4nM$). Yeast cells expressing G_q , G_{14} , and G_{16} and EMR2 without its N-terminal fragment grew more than cells expressing full-length receptor¹¹⁹. Our data supports EMR2 recruitment of G_q , G_{11} , and G_{15} , and we are the first to show the dose-dependent recruitment of these G-proteins. Unfortunately, we did not have a G_{14} BRET sensor, therefore future studies will have to be done to support their data¹⁰¹. As mentioned in the introductory chapter, G_{16} is the human homolog of the murine G-protein G_{15} , therefore it is not surprising EMR2 can couple to both G

proteins^{27,28}. EMR2 was previously shown to couple to G₁₆, where its signaling was found to be important for macrophage differentiation and proinflammatory responses¹²⁸. Therefore, EMR2 coupling to the G_{q/11} family of G-protein likely contributes to its role in regulating immune cell functions such as macrophage differentiation and proinflammatory responses, and neutrophil migration, degranulation, and cytokine secretion^{50,80,81,128}.

EMR2 dose-dependently recruited G_{i1} (EC₅₀=79.28nM), G_{i2} (EC₅₀=115.4nM), G_{i3} (EC₅₀=123.9nM), G_{oA} (EC₅₀=75.90nM), G_{oB} (EC₅₀=144.9nM), G_z (EC₅₀=249.5nM) and G_{gustducin} (EC₅₀=100.9nM) (Fig 14). Our data are consistent with results from the study showing that yeast cells expressing G_{i1}, G_{i3}, G_o, and G_z and EMR2 without its N-terminal fragment grew more than full-length receptor expressing cells¹¹⁹. However, we are the first to show EMR2 coupling to G_{i2}, both G_{oA} and G_{oB}, and G_{gustducin}, as well as the dose-dependent coupling of EMR2 to the G_{i/o} family of G-proteins. EMR2 coupling to G_{i1-3} and G_z likely contribute to its roles in macrophage differentiation and proinflammatory responses, as well as neutrophil migration, degranulation, and cytokine secretion^{50,80,81,128}. Similar to CD97, the ability for EMR2 to couple with G_{oA} and G_{oB} is odd as the receptor is not known to be expressed in neurons or neuroendocrine cells⁵⁰. However, EMR2 is also reported to be involved in glioblastoma, a brain cancer of the neuronal immune cell astrocytes⁵³. Therefore, our results suggest a possible yet undetermined function of EMR2 in the CNS. The ability of EMR2 to dose-dependently recruit G_{gustducin} is odd considering that the receptor is not known to be expressed in the tongue or in nutrient sensing cells of the gastrointestinal tract^{50,127}. Therefore, our results may suggest a possible yet undiscovered role for EMR2 in the gustatory system.

As shown in figure 14 EMR2 dose-dependently recruited G_{sL(Long)} (EC₅₀=155.6nM), and G_{sS(short)} (EC₅₀=74.45nM). Our data is supported by the fact that yeast cell expressing G_s and EMR2 without its N-terminal fragment grew more than cells expressing full-length receptor¹¹⁹. The ability of EMR2 to couple to both the G_{i/o} and G_s families of G-proteins at first may seem odd. However, many other well studied receptors, such as the β₂ adrenergic, histamine, serotonin, and glucagon receptors, have been shown to couple to both the G_{i/o} and G_s families of G-proteins¹²⁹. Further, another aGPCR, GPR98

(ADGRV1) can couple to both the $G_{i/o}$ and G_s families of G-proteins^{53,130,131}. However, the role of EMR2 G_s coupling remains a mystery as this signaling would likely antagonize many of its known functions in immune cells^{50,80,81,128}. Therefore, future experiments will need to be done to determine the relevance of EMR2 G_s signaling.

3.2.4 GPR56 activation results in the recruitment of β -arrestin and a variety of G-proteins

By creating a chimeric trypsin activated PAR2-GPR56 receptor, where the first 36 amino acids of PAR2 were fused to the C-terminal fragment of GPR56, we were able to study the recruitment of 16 effector proteins from the 5 major signaling pathways downstream of GPCRs. As shown in figure 15 GPR56 dose-dependently recruited both β -arrestin 1 ($EC_{50}=25.00nM$) and 2 ($EC_{50}=24.41nM$). The interaction of GPR56 with β -arrestin 2 was previously shown using co-immunoprecipitation with GPR56 with and without its N-terminal fragment⁶². These researchers also showed that although removal of the GPR56 stalk region did decrease the interaction of β -arrestin 2 with GPR56, it was still significantly higher than levels seen with the full-length receptor⁶². Therefore, the recruitment of β -arrestin 2 to GPR56 seems to be the result of not only tethered ligand binding but also receptor conformational change⁶². Our data supports GPR56 recruitment of β -arrestin 2, and we are also the first to show the dose-dependent recruitment of β -arrestin 1 and 2.

GPR56 dose-dependently recruited both G_{12} ($EC_{50}=59.14nM$), and G_{13} ($EC_{50}=78.16nM$) (Fig 15). The ability of GPR56 to dose-dependently couple to $G_{12/13}$ has been previously documented^{58,59,62}. Using the tethered ligand mimicking peptide TYFAVLM-NH₂, Stoveken et al showed that GPR56 dose-dependently activated G_{13} . They did so by measuring the rate of exchange of GDP for GTP γ S, a non-degradable form GTP, on G_{13} ⁵⁹. Using the SRE reporter gene assay, Kishore et al showed that GPR56 without its N-terminal fragment produced significantly higher SRE luminescence than cells expressing full-length receptor. They also showed that this increase in SRE luminescence was tethered ligand dependent, as removal of the GPR56 stalk region abolished this signal⁶². However, it should be noted that activation of the SRE reporter gene could also come from activation of the $G_{q/11}$ family of G-proteins²⁷. Our data supports GPR56

coupling to $G_{12/13}$, and we also for the first time show the dose-dependent coupling of GPR56 to G_{12} . GPR56 coupling to $G_{12/13}$ is likely involved in its metastatic role in various cancers, such as colorectal, melanoma and prostate⁵³. $G_{12/13}$ signaling is also likely involved in the role GPR56 plays in platelet activation and immune cell compartmentalization^{58,87}. Finally, GPR56 $G_{12/13}$ signaling is also likely involved in its role in the development of the cerebral cortex, where it guides the migration of newly formed neurons to their proper location on the pial membrane^{82,83,85}.

As shown in figure 15 GPR56 dose-dependently recruited G_q ($EC_{50}=85.33nM$), G_{11} ($EC_{50}=65.99nM$) and G_{15} ($EC_{50}=17.79nM$). The association of GPR56 with $G_{q/11}$ has been previously shown using co-immunoprecipitation and mass spectroscopy¹³². In this study, Little et al showed that the interaction of GPR56 with $G_{q/11}$ was stabilized in a molecular scaffold by the tetraspanin proteins CD9 and CD81. Our data supports the coupling of GPR56 to G_q and G_{11} , and we are the first to show the dose-dependent recruitment of these G-proteins. Interestingly, we also show that GPR56 is a high affinity recruiter of G_{15} . As mentioned in chapter 1 G_{15} shows expression restricted to hematopoietic cells^{27,28}. GPR56 has been shown to be important for platelet activation⁵⁸. As $G_{q/11}$ signaling is important for the activation of platelets it is not surprising GPR56 would signal through G_q , G_{11} , and the hematopoietic cell restricted G-protein G_{15} ^{27,28,58,113}. However, when Yeung et al applied the GPR56 tethered ligand mimicking peptide TYFAVLM-NH₂ to platelets they were not able to see an increase in intracellular Ca²⁺. This may be explained by work done by Kishore et al, where they showed GPR56 receptors without its N-terminal fragment and without its stalk region both had significantly higher NFAT reporter gene luminescence than full-length receptors. This suggests that GPR56 $G_{q/11}$ signaling is mediated by a receptor conformational change explaining why Yeung et al did not see an increase in intracellular Ca²⁺ with TYFAVLM-NH₂⁶².

GPR56 dose-dependently recruited G_{i1} ($EC_{50}=148.5nM$), G_{i3} ($EC_{50}=151.5nM$), G_{oA} ($EC_{50}=47.23nM$), and G_{oB} ($EC_{50}=69.99nM$) (Fig 15). As the EC_{50} 's of G_{i2} ($EC_{50}=841.5nM$), G_z ($EC_{50}=892.0nM$) and $G_{gustducin}$ ($EC_{50}=702.3nM$) were high and response were small and variable we conclude that GPR56 likely does not couple to these

G-proteins (Fig 15). The coupling of GPR56 to the $G_{i/o}$ family of G-proteins was recently shown by Yeung et al. The GPR56 tethered ligand mimicking peptide TYFAVLM-NH₂ was able to decrease forskolin elevated levels of cAMP in platelets⁵⁸. GPR56 coupling to $G_{i/o}$ in platelets is consistent with its role in platelet activation⁵⁸. Our data supports GPR56 coupling to G_{i1} and G_{i3} , and these G-proteins likely contribute to its role in platelet activation^{27,58,113}. We are the first to show GPR56 coupling to G_{oA} and G_{oB} , and this coupling is consistent with its role in brain development and expression in oligodendrocytes, glia cells, microglia, and neural progenitor cells^{50,82,83,85}.

As shown in figure 15 GPR56 dose-dependently recruited $G_{sL(Long)}$ ($EC_{50}=52.52nM$), and $G_{sS(short)}$ ($EC_{50}=49.84nM$). We are the first to report the coupling of GPR56 to the G_s family of G-proteins. The coupling of GPR56 to G_s is curious as it would seem to antagonize its G_i signaling in platelet activation^{27,58,113}. However, as mentioned in the discussion of EMR2 other receptors do display this signaling phenomenon and future studies will need to be done to determine the functional role of GPR56 G_s signaling^{119,129-131}.

3.2.5 BAI1 activation results in the recruitment of β -arrestin and a variety of G-proteins

By creating a chimeric trypsin activated PAR2-BAI1 receptor, where the first 36 amino acids of PAR2 were fused to the C-terminal fragment of BAI1, we were able to study the recruitment of 16 effector proteins from the 5 major signaling pathways downstream of GPCRs. As shown in figure 16 BAI1 dose-dependently recruited both β -arrestin 1 ($EC_{50}=37.42nM$) and 2 ($EC_{50}=25.72nM$). The interaction of BAI1 with β -arrestin 2 has been previously shown using co-immunoprecipitation of BAI1 with and without its N-terminal fragment⁶². These researchers also showed that removal of the BAI1 stalk region did not decrease its interaction with β -arrestin 2⁶². Therefore, the interaction of BAI1 with β -arrestin 2 seems to be the result of a receptor conformational change and not the binding of its tethered ligand⁶². Our data supports the coupling of BAI1 with β -arrestin 2, and we are the first to show the dose dependent coupling to β -arrestin 1 and 2.

BAI1 dose-dependently recruited G_{12} ($EC_{50}=73.79nM$), and G_{13} ($EC_{50}=39.60nM$) (Fig 16). The interaction of BAI1 with $G_{12/13}$ has been previously shown. BAI1 receptors without their N-terminal fragment had increased RhoA activity and SRE reporter gene luminescence compared to cells expressing full-length receptor^{62,133}. Kishore et al also showed that removal of the BAI1 stalk region did not decrease SRE reporter gene luminescence. Therefore, the interaction of BAI1 with $G_{12/13}$ seems to be the result of a receptor conformational change and not the binding of its tethered ligand⁶². Kishore et al also showed the direct interaction of BAI1 with G_{13} by immunoprecipitation⁶². Our data supports the coupling of BAI1 to $G_{12/13}$ and we are the first to show the dose-dependent recruitment of these G-proteins. BAI1 $G_{12/13}$ is likely involved in its roles in regulating macrophage phagocytosis of bacterial and apoptotic cells, myoblast fusion in muscle fibers, and synaptogenesis^{89-92,133}.

As shown in figure 16 BAI1 dose-dependently recruited G_q ($EC_{50}=179.4nM$), G_{11} ($EC_{50}=50.66nM$), and G_{15} ($EC_{50}=164.3nM$). The interaction of BAI1 with $G_{q/11}$ has been inferred, as BAI1 receptors without their N-terminal fragment had increased NFAT reporter gene luminescence than cells expressing full-length receptor⁶². However, it should be noted that activation of the NFAT receptor gene can also occur through activation of the $G_{12/13}$ family of G-proteins²⁷. Kishore et. al., also showed that removal of the BAI1 stalk region did not decrease NFAT reporter gene luminescence. Therefore, the interaction of BAI1 with $G_{q/11}$ seems to be the result of a receptor conformational change and not the binding of its tethered ligand⁶². Our data supports the coupling of BAI1 to $G_{q/11}$, and we are the first to show the dose-dependent interaction of BAI1 with G_q , G_{11} , and G_{15} . BAI1 $G_{q/11}$ signaling is likely involved in its roles in regulating macrophage phagocytosis of bacterial and apoptotic cells, myoblast fusion in muscle fibers and synaptogenesis^{89-92,133}.

BAI1 dose-dependently recruited G_{i1} ($EC_{50}=44.33nM$), G_{i2} ($EC_{50}=82.13nM$), G_{i3} ($EC_{50}=48.37nM$), G_{oA} ($EC_{50}=33.26nM$), G_{oB} ($EC_{50}=47.93nM$), G_z ($EC_{50}=91.97nM$), and $G_{gustducin}$ ($EC_{50}=109.5nM$) (Fig 16). We are the first to show the interaction of BAI1 with the $G_{i/o}$ family of G-proteins. BAI1 G_i signaling is likely involved in its roles in regulating macrophage phagocytosis of bacterial and apoptotic cells, myoblast fusion in

muscle fibers, and synaptogenesis^{89–92,133}. BAI1 recruitment of G_{oA} and G_{oB} is not surprising as it is expressed in astrocytes, microglia, and neurons⁵⁰. The ability of BAI1 to dose-dependently recruit $G_{\text{gustducin}}$ is odd considering that the receptor is not known to be expressed in the tongue or in nutrient sensing cells of the gastrointestinal tract^{50,127}. Therefore, our results may suggest a possible yet undiscovered role for BAI1 in the gustatory system.

As shown in figure 16 BAI1 dose-dependently recruited $G_{sL(\text{Long})}$ ($EC_{50}=178.2\text{nM}$), and $G_{sS(\text{short})}$ ($EC_{50}=83.11\text{nM}$). We are the first to report the interaction of BAI1 with the G_s family of G-proteins. The coupling of BAI1 to G_s is curious as it would seem to antagonize its G_i signaling in macrophage phagocytosis of bacterial and apoptotic cells, myoblast fusion in muscle fibers and synaptogenesis^{89–92,133}. However, as mentioned in the discussion of EMR2 and GPR56 other receptors do display this signaling phenomenon and future studies will need to be done to determine the functional role of BAI1 G_s signaling^{119,129–131}.

3.2.6 Utility of PAR2-aGPCR chimeric receptors

Overall, our results support the idea that our PAR2-aGPCR chimeric receptors can be more broadly used to study the signaling and function of all members of the aGPCR family. By analyzing studies done on trypsin and thrombin cleavage site specificities we were able to predict that the C-terminal fragments of aGPCRs could be unmasked by proteolytic cleavage^{108,111}. By fusing the first 36 amino acids of PAR2 to the C-terminal fragment of aGPCRs, the receptors could be time dependently activated by increasing concentrations of trypsin. We tested this hypothesis by creating PAR2-CD97, EMR2, GPR56, and BAI1 chimeric receptors, where 3/4 of these receptors had unique trypsin cleavage sites. We are confident that our four PAR2-aGPCR chimeric receptors were all effectively cleaved by trypsin as they dose dependently recruited a variety of effector proteins. With the lack of synthetic agonists and tools for activating aGPCRs with their natural mechanism of action, our chimeric receptors represent an exciting new method for studying aGPCR signaling and function.

3.2.7 SSFAILMAH-NH₂ is a potent CD97 activating tethered ligand mimicking peptide

We first validated that the TANGO assay would be a useful screening assay for our lab's purposes. As we were planning on using the assay for testing potential tethered ligand mimicking peptides, we validated the assay by using the well-studied PAR2 tethered ligand mimicking peptide SLIGRL-NH₂. As shown in figure 17 SLIGRL-NH₂ dose dependently activated PAR2 with a similar EC₅₀ (11.1μM) for β-arrestin 2 recruitment as we have previously reported¹⁰⁰. Now confident the TANGO assay was an effective screening tool we tested our predicted CD97 activating peptide SSFAILMAH-NH₂. As shown in figure 17 SSFAILMAH-NH₂ dose dependently activated CD97 with an EC₅₀ of 17.28μM. As mentioned in chapter 2, our PAR2-aGPCR chimeric receptors are more ideal screening tools than full-length receptors as they eliminate the uncontrollable N-terminal fragment removal that can occur through regular cellular processes. Therefore, we next used our PAR2-CD97 chimeric receptor to test the ability of SSFAILMAH-NH₂ to activate CD97 using the BRET1 assay. As shown in the lower two graphs of figure 17 SSFAILMAH-NH₂ was able to cause the dose dependent recruitment of both β-arrestin 1 (EC₅₀=22.86μM) and 2 (EC₅₀=78.29μM). As the TANGO assay measures β-arrestin 2 recruitment it might seem odd at first that the EC₅₀'s of SSFAILMAH-NH₂ are different between the TANGO and BRET1 assays but are similar between the two assays for SLIGRL-NH₂. However, the TANGO receptor constructs have the tail of the vasopressin receptor 2 to boost β-arrestin recruitment^{102,103,106}. Therefore, it would be expected that the TANGO assay would underestimate the EC₅₀ of β-arrestin 2 recruitment for receptors, explaining our results for SSFAILMAH-NH₂. However, as the PAR receptors are very strong recruiters of β-arrestin this may explain why the EC₅₀ of SLIGRL-NH₂ β-arrestin 2 recruitment are similar between the two assays. Therefore, both our TANGO assay and BRET1 assay data support that SSFAILMAH-NH₂ is a potent CD97 activating tethered ligand mimicking peptide. It also supports that our method for predicting aGPCR tethered ligand mimicking peptides is quite effective, as we were able to predict a very potent CD97 activating peptide on our first attempt. SSFAILMAH-NH₂ is now the second most potent tethered ligand mimicking peptide to be reported^{59-61,93,94,134}.

3.2.8 Future experiments

As validating our PAR2-aGPCR chimeric receptor design has been such a success, it opens the door to many years of future study. First, we plan to support the results of our G-protein recruitment data by performing three second messenger-based assays. As all four of our chimeric receptors dose dependently recruited the $G_{q/11}$ family of G-proteins we plan to use a fluorescence based Ca^{2+} assay to support our observations, as we have done previously⁹⁶. To support our observation that all four chimeric receptors recruited the $G_{i/o}$ family of G-proteins we plan to use the GLO-sensor assay with forskolin to pre-elevate cAMP levels to block the effects of G_s ¹³⁵. If our observations are correct, then trypsin treatment of our chimeric receptors should be able to elicit a concentration dependent decrease in the rate of cAMP production. We plan to use a similar approach to show that EMR2, GPR56, BAI1 can recruit the G_s family of G-proteins. However, we will use pertussis toxin to inhibit G_i and see if our chimeric receptors can dose dependently increase the rate of cAMP production¹³⁵. The final second messenger assay we plan to do is measuring the activation of ERK/MAPK, as we have done previously¹⁰⁰. We plan to measure the ability of our chimeric receptors to dose dependently increase the amount of phosphorylated ERK using western blots¹⁰⁰.

Another exciting project we plan on pursuing is the study of aGPCR internalization. As control of receptor activation has been difficult to achieve, little study has been done on aGPCR internalization. Having this future project in mind when designing our chimeric receptors, we added restriction enzyme cut sites to put in an N-terminal red fluorescent protein (RFP) tag. Therefore, by using receptors N-terminally tagged with RFP and C-terminally tagged with YFP we can specifically track receptors being activated by our trypsin treatment through the different stages of their internalization pathway. Further, this N-terminal RFP tag on our chimeric receptors can also be used as another way of proving they are being properly cleaved by trypsin. As the activation of aGPCRs is irreversible, similar to the PARs, we would expect them to traffic in a similar manner. PARs are known to traffic almost exclusively to the lysosomes for degradation and not back to the membrane for further rounds of activation¹³⁶. Therefore, we would hypothesize that aGPCRs would follow a similar internal trafficking pathway.

An ongoing interest of our lab is to understand where and how β -arrestin interacts with tethered ligand activated receptors. In the past we have determined important PAR2 and PAR4 β -arrestin interacting residues through the mutation of predicted phosphorylation sites and interactions predicted by molecular modeling^{97,100}. We plan to use a similar approach to attempt to determine important β -arrestin interacting residues in CD97, EMR2, GPR56, and BAI1 by using our chimeric receptors.

Our lab is also interested in identifying the exact residues forming the tethered ligands of aGPCRs⁹⁶. Therefore, we plan on doing a series of mutations to the stalk regions of our PAR2-CD97, EMR2, GPR56, and BAI1 chimeric receptors to determine the sequence of these receptors tethered ligands. In a recent book chapter (Mirka and Ramachandran, In press) we were able to predict a number of conserved molecular switches involved in aGPCR activation, which were determined through analysis of the recently solved structure of GPR97⁶⁵. In brief, the toggle switch residue W^{6.48} was found to serve a similar function as W^{6.53} and is conserved in 31/33 aGPCRs⁶⁵. The PIF motif was found to be replaced with a F^{3.44}M^{3.47}XW^{6.53} upper quaternary core motif that was found to serve an important role in aGPCR activation⁶⁵. The D(E)RY motif was found to be replaced with a H^{3.53}L^{3.54}Y^{3.55} motif that was also found to serve an important role in aGPCR activation⁶⁵. However, mutational studies testing the importance of these residues in receptor activation have only been done on GPR97 and GPR126, two members of the G subfamily⁶⁵. Therefore, we plan to perform similar mutations on members of the E subfamily CD97 and EMR2, on GPR56 which is a member of the G subfamily, and on BAI1 which is a member of the B subfamily using our chimeric receptors. These mutational studies will show whether these conserved residues have important functions in aGPCR activation in general or if their importance is restricted to the G subfamily.

Our work here with four aGPCRs also provides guidance for creating the full panel of 33 trypsin activated PAR2-aGPCR chimeric receptors. We hope to develop this as an open-source platform of constructs that us and other labs can use to study aGPCR signaling and function. This panel of constructs will also be useful for future small molecule library drug screens. This is because full length aGPCRs can be activated by uncontrollable cellular processes, which could cause a lot of false positives in drug screening. Unlike

full length aGPCRs our chimeric receptors can only be activated by trypsin mediated proteolytic cleavage, therefore removing this uncontrollable error.

The polycystin family of receptors share a similar structure and mechanism of action to aGPCRs¹³⁷. The receptors are autoproteolytically cleaved during biosynthesis into N-terminal and C-terminal fragments, which remain non covalently associated through the interaction of the β -13 strand with the GAIN domain¹³⁷. As they share a similar structure and mechanism of action this family of 5 atypical GPCRs are also difficult to study¹³⁷. Therefore, another future application of our approach could be to make PAR2-polycystin chimeric receptors to study the signaling and function of this receptor family.

In the future we plan to use our CD97 tethered ligand mimicking peptide SSFAILMAH-NH₂ in the same G-protein recruitment and second messenger assays to support our results with trypsin activation. The use of the peptide will also allow us to determine which signaling pathways are tethered ligand dependent and which ones may instead be due to a receptor conformational change.

We also plan on using our method of predicting tethered ligand mimicking peptides to create agonists for other receptors, such as BAI1 and EMR2. Similar to GPR56 and CD97, BAI1 does not have any predicted turn elements in its stalk region (Fig 9). Therefore, a peptide corresponding to the first 9 amino acids of the BAI1 stalk region, STFAILAQL-NH₂, could be the sequence of a future BAI1 tethered ligand mimicking peptide. EMR2 does have a predicted turn element in its stalk region and would therefore likely require a longer peptide, SSFAILMAHYDVQEED-NH₂, which includes this turn element.

The use of our PAR2-aGPCR chimeric receptors in in-vitro and in-vivo studies are limited by the fact that PAR1 and PAR2 are also activated by trypsin and must therefore be either inhibited or knocked out⁴⁸. However, as long as our tethered ligand mimicking peptides do not cross react with other aGPCRs they can be used in functional in-vitro and in-vivo studies. The tethered ligand mimicking peptides of receptors in the same subfamily have been shown to cross react⁶⁰. Therefore, we plan to use the TANGO assay

to screen SSFAILMAH-NH₂, TYFAVLM-NH₂, and our future BAI1 and EMR2 tethered ligand mimicking peptides against all 33 aGPCRs to test for specificity.

Another project we plan on pursuing in the near future is the development of aGPCR antagonists. Due to the difficulty of studying tethered ligand activated receptors, a class of compounds known as pepducins were designed to help study the PARs¹³⁸⁻¹⁴⁰. Pepducins are intracellular targeting palmitoylated peptides derived from a receptors intracellular loops or transmembrane domains¹³⁸⁻¹⁴⁰. By mimicking the intracellular domains of a receptor, they are able to bind and stabilize the inactive state¹³⁸⁻¹⁴⁰. Although pepducins were originally developed to study the PARs, they have since been used to study many GPCRs¹³⁸⁻¹⁴⁰. Therefore, in the future we plan on making pepducins to study the signaling and function of our four aGPCRs of interest.

3.2.9 Limitations

The PAR2-aGPCR chimeric receptors have enabled us to study receptor proximal signaling events for four different adhesion GPCRs for the first time. There are however some limitations to our approach. Firstly, several concentration effect curves do not saturate, limiting our ability to quantitatively compare coupling of the different signaling pathways. We used up to 300nM trypsin as concentrations higher than this cause non-specific responses due to the lifting and proteolytic lysis of cells¹⁴¹ and can result in activation of PAR1. Nevertheless, these constructs will enable us to develop additional pharmacological tools targeting each receptor that will allow such quantitative assessment.

The main limitation of aGPCR tethered ligand mimicking peptides is their solubility, and SSFAILMAH-NH₂ is no exception^{59-61,93,94}. Due to the cytotoxic effects of DMSO it is recommended to limit its concentration to less than 0.1% in most cellular assays¹⁴². However, most aGPCR tethered ligand mimicking peptides require at least 3-5% DMSO to remain soluble in solution^{59-61,93,94}. Therefore, in the future we plan to optimize the sequence of SSFAILMAH-NH₂, TYFALM-NH₂, and our future BAI1 and EMR2 tethered ligand mimicking peptides to improve their solubility and activity. Recently the GPR64 tethered ligand mimicking peptide, TSGILLDLSRTSLP-NH₂, was optimized to

improve its activity 170-fold¹³⁴. The only changes made were substitution of the first residue, T to V, and the third residue, F to Phe(4-Me)¹³⁴. Although these modification did not improve the solubility of the peptide, they did drastically improve its activity from the high to low μM range¹³⁴. Therefore, when optimizing our peptides, we will keep these modifications in mind. When designing the tethered ligand mimicking peptides for the PARs it was found that peptides mimicking the murine tethered ligand were more potent than ones mimicking the human sequence⁴⁸. However, no one has tried mimicking the murine tethered ligand sequence when generating aGPCR tethered ligand mimicking peptides. Therefore, in the future when optimizing our tethered ligand mimicking peptides, we will test if mimicking the murine sequence improves activity.

Curriculum Vitae

Name: Victor Mirka

Post-secondary Education and Degrees: The University of Western Ontario
London, Ontario, Canada
Masters of science
Degree planned to be conferred October 2021
2019-2021

The University of Western Ontario
London, Ontario, Canada
Bachelor of Medical Science
Honors specialization: Physiology and Pharmacology
Degree conferred June 2019
2015-2019

Honours and Awards: Province of Ontario Graduate Scholarship
2019-2021

Related Work Experience: Teaching Assistant
The University of Western Ontario
Pharm 3620
2020-2021

Teaching Assistant
The University of Western Ontario
PhysPharm 3000E
2019-2020
