Abstract

Although viruses are obligate intracellular parasites, they have their own evolutionary trajectory, their genomes are in a constant battle to overcome the defenses of the host. This thesis investigates the role of the small HERC family of proteins in the battle against two deadly viruses: Human Immunodeficiency Virus -1 (HIV) and Zaire ebolavirus (EBOV). Although their discovery occurred decades ago, little knowledge is available about the small HERC family, their functions, and modes of interactions with other cellular proteins. In the first chapter, the structural evolution of the small HERC family and related functional changes that have occurred over time are explored. We investigate the induction of the small HERC protein by Interferon β and the antiviral activity of HERC5 and HERC6, the most recently emerged members of the small HERC family. We discovered that an ancient form of the HERC5 protein present in the fish species coelacanth has the ability to inhibit the simian immunodeficiency virus (SIV) but not HIV in a similar manner to the human HERC6 protein, whereas the human HERC5 protein inhibits both viruses potently. Focusing more on the interferon induced HERC5 and HERC6 and their contribution to innate immunity, the second chapter focuses on HERC6 and single nucleotide polymorphism which enhances its ability to restrict HIV-1. This SNP confers antiviral activity against HIV-1 in vitro and correlates with disease progression to AIDS in an infected cohort in Uganda. The third chapter illustrates the ability of HERC5 to restrict Ebola virus structural protein VP40 by degrading its RNA, solidifying it as an important weapon in the arsenal of innate immunity. Unfortunately, the glycoprotein of EBOV is able to counteract the restrictive ability of HERC5. The small HERC family and especially HERC5 and HERC6 are emerging as potent antiviral molecules which can combat diverse families of highly pathogenic viruses such as HIV and Ebolavirus. This work advances the knowledge of the small HERC family and more generally the multifaceted ways the innate immune system responds to viral infections in humans.

Keywords

Innate immunity, Restriction factors, Interferon stimulated genes (ISG), Human Immunodeficiency Virus -1, Simian Immunodeficiency Virus, Ebola virus, Small HERC family, single nucleotide polymorphisms, HERC3, HERC4, HERC5, HERC6, ISG15.

Summary for Lay Audience

Innate immunity is the body's ancient and immediate form of defense against harmful organisms. The subtle workings of this protection have evolved over millennia to combat diverse pathogens such as viruses, bacteria, and parasites. Activation of the interferon response is one such defense which produces various proteins to combat these deadly pathogens. Unfortunately, pathogens have developed their own methods of overcoming the immune system, to allow the establishment of the infection. In this thesis, I will discuss the various functions of the small HERC family of proteins, a subset of which are activated by the interferon response to fight a variety of viruses. HERC5 and HERC6, two of the most evolutionarily recent members of the small HERC family are interferon induced and have potent antiviral properties. HERC5 has the ability to inhibit the replication of multiple viruses including Human Immunodeficiency virus (HIV-1) and Ebola virus (EBOV) through various mechanisms of actions. First, through its ability to directly modify viral proteins it can inhibit assembly of viral particles. Second, it can inhibit the exit of viral RNA from the nucleus prohibiting the virus from making its structural proteins and forming new progeny. Lastly, to combat EBOV, HERC5 inhibits the production of its structural protein VP40 through the degradation of its RNA. Interestingly, EBOV, via its envelope protein, is able to inhibit the antiviral activities of HERC5. Another antiviral member of the small HERC family, HERC6, is not able to inhibit HIV-1 replication, however, a single amino acid change can restore this potency. The study of the immune system allows for increased understanding of how the body functions to combat viruses and how viruses have evolved elaborate defenses to continue infecting humans. This knowledge would contribute to the development of therapies and treatments to enhance the immune defenses against viruses or conversely, discover novel ways to inhibit viral replication through inhibitions of their functions.

Co-Authorship Statement

In Chapter 1 the section 1.3.5 ISG15 and ISGylation was partially published in: Mathieu NA, Paparisto E, Barr SD, Spratt DE. HERC5 and the ISGylation Pathway: Critical Modulators of the Antiviral Immune Response. *Viruses*. 2021 Jun 9;13(6):1102. doi: 10.3390/v13061102. (Appendix 1)

Chapter 2 of this thesis was published in: *J Virol*. 2018 Jul 1; 92(13): e00528-18. (Appendix 2). SD. Barr and MW Woods were responsible for generating Figure 2.1, 2.2 and 2.6. MW. Woods generated Figure 2.3F and 2.4D. MD. Coleman generated Figure 2.3C and HP Kohio generated Figure 2.4A and B.

In Chapter 3, Figure 3.1 C, D, and E was completed by S. Barr. Figure 3.3 was completed by S. Barr in collaboration with Seyed A. Moghadasi, and Divjyot S. Kochar.

Chapter 4 of this thesis was published in: *Cells* 2021, 10(9), 2399; <https://doi.org/10.3390/cells10092399>. (Appendix 1). Figure 4.1 B was adapted from (Watt et al., 2014), copyright © American Society for Microbiology, *J. Virol*. 88, 2014, 10,511–10,524, doi:10.1128/JVI.01272-14. Figure 4.2 F and G was generated by NR. Hunt, Figure 4.2 H was generated by EJ. Di Gravio. Figure 4.3 and Figure 4.5 A and B were generated by NR. Hunt in collaboration with EJ. Di Gravio. Figure 4.4 was generated by DS. Labach in collaboration with E. Paparisto.

Acknowledgments

This PhD is dedicated to my daughter Mikela. My little miracle baby which brightens even the cloudiest of days. There are hundreds of people who have helped me with my PhD journey and if I have forgotten to mention your name, please know it is not from lack of appreciation but due to the loss of brain cells in the process. First, I would like to thank Dr. Barr for the opportunity to work with him and for his unwavering support through all the ups and downs which are research, exciting results, failed experiments, rejected and eventually published papers, and lab life in general. Dr. Barr, words can never describe how thankful I am for all you have done for me in the past years. A great thank you to my advisory committee Dr. Dekaban and Dr. Heit for keeping me on track during my thesis and especially Dr. Heit for all the helpful edits in this thesis. Secondly, I'd like to thank my family. Your support and encouragement have kept me going through the downs and celebrated with me through the ups. Without you I would never have been able to get through this. A giant thanks to Mike, your passive aggressive sarcasm pushed me to the finish line more than you know (we got a PhD!!). I owe a great debt to my grandmother Nena Bia; without you I would never have considered a career in science. To the rest of my family Merita, Emil, and Adela thank you for not giving up on me even though the end got a bit hairy. Thank you to Aurora and Vaso, Kujtimi, Pandora, Oresti and Erzhi, Katina, for always being there for me and not asking "Are you done yet?". Third, I would like to thank all the Barr lab members I have had the pleasure of working with through the years. They have contributed to this work both directly with experiments and indirectly with moral support. Thank you Matt, Macon, Divy, Nina, Eric, Taryn, Mackenzie, Arad, Adam, McShane, Melodie, Keman, Dan, and Nicole. Thank you also to all the friends I have made in grad school, your friendship has helped me immensely throughout this journey. Thank you to Amanda and Jack my first friends at M&I, Colin and Katie, Arad, Carol, Ankita my gym buddy, Rahul and Darsh you always put a smile on my face, Josh, Yodit, Kate, Rajiv, Mariya and Stephen, Emmanuel, as well as everyone who helped make IIRF 2018 a huge success. Last but not least, I would like to thank all the faculty and staff in the Department of Microbiology and Immunology for their guidance, support, and funding throughout my studies.

Chapter 1

1 Introduction

We share our world with a multitude of other organisms: some beneficial to us, most neutral, and a small subset which are pathogenic. Although viruses are obligate intracellular parasites, they have their own evolutionary trajectory, their genome in a constant battle to overcome the defenses of the host. Humans and pathogenic viruses have co-evolved, developing defense mechanisms to invade and resist each other. This chapter will provide a brief introduction of two harmful viruses to humans: Zaire ebolavirus (EBOV) and Human Immunodeficiency Virus Type 1 (HIV) and the way that the innate immune system has simultaneously evolved to detect and eliminate these pathogens. Special attention will be given to the small HERC family of which two members HERC5 and HERC6 are interferon-induced and defend against diverse families of viruses. A portion of section 1.3.5 was previously published in *Viruses* (Mathieu NA, Papparisto E, Barr SD, Spratt DE. HERC5 and the ISGylation Pathway: Critical Modulators of the Antiviral Immune Response. *Viruses*. 2021 Jun 9;13(6):1102. doi: 10.3390/v13061102.).

1.1 Global Impact of HIV and Ebola virus

After experiencing the global COVID-19 pandemic, it is difficult to deny the power of viruses to affect our lives. Viral outbreaks impact not only the lives of those infected but the lives of the community and the country where they occur. The far-reaching socio-economic disruptions can last for years after the viral outbreak has been contained^{1,2}.

The largest recorded *Ebolavirus* outbreak is the West African epidemic between 2014 and 2016 which infected 28,610 people and caused 11,308 deaths in the region^{3,4}. This was caused by the Zaire strain of the *Ebolavirus* (also referred to as Ebola virus (EBOV)) rapidly spreading from a rural region in Guinea to the capital city of Conakry, which facilitated the spread to the neighboring countries of Liberia and Sierra Leone^{3,5-7}. Until

this outbreak, *Ebolaviruses* were considered an exotic pathogen of little consequence to public health³.

Ebola virus disease (EVD) caused by the Ebola virus devastated the West African economy and caused a monetary loss of approximately 53.19 billion dollars^{1,2,9}. The burden placed on the healthcare system likely resulted in the loss of an additional ~10,000 lives, mostly of people who had other serious health conditions such as HIV, tuberculosis, or malaria and could not access care^{10,11}. During this epidemic, healthcare workers were amongst the most affected, around 8 % of which were lost to the Ebola virus infections^{6,12}. Due to the vulnerability of the region, recovery was slow and the impact of the outbreak long-lasting. In addition to the death and economic devastation caused by EVD, survivors of the disease are left with life-long disabilities such as autoimmune disorders, ocular problems, encephalitis, neurological disorders, and musculoskeletal pains. This constellation of symptoms is collectively referred to as “Post Ebola Syndrome”^{7,13,14}. *Ebolavirus* outbreaks continue to occur in Africa despite the availability of a vaccine. Currently, there is an outbreak in the Democratic Republic of Congo, making it the sixth outbreak in 5 years¹⁵. In addition to the treatment challenges, harassment of healthcare workers by armed groups, lack of public trust in the health system, and a volatile political climate compound the difficulty in containing this disease^{6,15}. The increase in outbreaks over the years, the severity of the disease, and the high socioeconomic cost warrants additional research focused on discovering new, affordable, and broad acting antiviral therapies.

While *Ebolavirus* epidemics occur mostly in the central and western African regions, the HIV pandemic has spread globally, leaving no country untouched¹⁶⁻¹⁸. Since the first AIDS cases were discovered in the 80's HIV has claimed more than 40 million lives¹⁶⁻²¹. As of 2021, more than 38.4 million people were living with HIV, 1.7 million of which are children under the age of 15^{22,23}. Although mortality has dropped almost 40 % since 2010, in 2021 650000 people died from AIDS related disease worldwide^{22,24}. In Canada, approximately 62,790 people were living with HIV in 2020, with 1,639 of those being

new cases^{25,26}. In addition to the devastating health impact this virus has on people living with HIV, it has a significant burden on the economy. This includes the labor force, ongoing government aid to organizations for providing antiretroviral therapy to patients and testing and prevention programs²⁶. The UNAIDS organization previously estimated that in 2020 approximately 26.2 billion dollars will need to be invested in the HIV/ AIDS response and prevention²⁴. However, since then funding has been diverted to other global crisis and the progress towards eradicating HIV is slowing rather than progressing²⁴.

Global efforts have focused on achieving the 95-95-95 goal set by UNAIDS by 2025^{24,27}. This strategy proposes to diagnose 95 percent of people infected with HIV, of those, 95 percent should be on antiretroviral treatment, and of those, 95 percent should achieve viral suppression. This goal was greatly helped by the initiation of treatment as soon as a positive diagnosis was confirmed, compared to the initiation of treatment only when the CD4 T cell count dropped below 200 cell per ml. In 2021, 85 percent of people infected with HIV knew their status, 75 percent of HIV positive people were accessing antiretroviral therapy, and of those, 92 percent achieved viral suppression globally²⁴. In Canada, the numbers are estimated to be more in line with the goals set out by the UN where 90 percent of HIV positive people are diagnosed, 87% were estimated to be on treatment and 95% of persons on treatment had a suppressed viral load²⁸. However, based on the stagnation of progress observed recently, as well as the detrimental impact of COVID-19 and continuous reduction in funding of HIV programs by various governments, most countries have been unable to meet these targets²⁴.

Both Ebolavirus and HIV disproportionately affect disadvantaged countries where treatment is harder to access. In addition to community outreach and continued education about prevention, new, easy to access treatments are needed to aid those who have already been infected with these viruses.

1.2 Viral Replication Cycle

Since viruses are obligate intracellular parasites, they require access and entry into the host cell to initiate and complete their replication cycle. There are certain fundamental steps that most viruses must go through to replicate: 1) it must attach to and enter the cell; 2), it must uncoat and shed the external layers to expose the genome to the replication machinery; 3) it must usurp the cellular machinery to make its own protein, and lastly 4) it must assemble into a new virion and exit the cell. Viruses have evolved to infect almost all forms of life from Archaea which live in thermal vents to bacterial cells to human organisms to plant cells²⁹⁻³².

Due to the lack of a common ancestor for all viruses, it is extremely difficult to classify them taxonomically. Currently, viruses are separated into families based on phenotypic characteristics such as structural proteins, susceptible host organisms, pathogenicity, and interactions with the immune system^{33,34}. Viral families are classified into seven different categories as delineated by the Baltimore system: I) double stranded DNA viruses, II) single stranded DNA viruses, III) double stranded RNA viruses, IV) positive sense single stranded RNA viruses, V) negative sense single stranded RNA viruses, VI) single stranded RNA viruses with reverse transcription abilities, and VII) DNA viruses with reverse transcription abilities^{33,34}.

More recently a megataxonomy proposal was put forth to the International Committee on Taxonomy of Viruses (ICTV). This new proposal classifies viruses into four realms of RNA Viruses and Reverse-Transcribing Viruses (*Riboviria*), ssDNA viruses (*Monodnaviria*), DNA viruses encoding vertical jelly-roll type major capsid proteins (*Varidnaviria*), and dsDNA viruses encoding HK97-type major capsid proteins (*Duplodnaviria*)³⁵.

The two viruses most discussed in this thesis are HIV and EBOV. HIV belongs to the realm *Riboviria*, Kingdom *Pararnavirae* Phylum *Artverviricota*, Class *Revtraviricetes*, Order *Ortervirales*, Family *Retroviridae*, Subfamily *Orthoretrovirinae*, Genus *Lentivirus*,

and species *Human immunodeficiency virus 1*³⁶. While *Ebolaviruses*, the causative agent of Ebola virus disease (EVD), belong to the realm *Riboviria*, kingdom *Orthornavirae*, phylum *Negarnaviricota*, subphylum *Haploviricotina*, class *Monjiviricetes*, order *Mononegavirales*, family *Filoviridae*, genus *Ebolavirus*. It has six species *Bombali ebolavirus*, *Bundibugy ebolavirus*, *Reston ebolavirus*, *Sudan ebolavirus*, *Tai Forest ebolavirus* and *Zaire ebolavirus*^{3,37}. Due to its high pathogenicity in humans, this thesis will focus on the *Zaire ebolavirus* (also referred to as Ebola virus or EBOV) although the replication steps are similar for the other members of the *Ebolavirus* genus^{3,4}.

While these viruses belong to separate families this thesis provides evidence that members of the small HERC family of proteins are capable of restricting their viral activity in distinct ways.

1.2.1 Human immunodeficiency virus replication cycle

The HIV virus is spherical in shape and contains a capsid core which encapsulates two copies of the viral genome consisting of 9-kB positive sense, unspliced, viral RNA (Figure 1.1 A)^{38,39}. This encodes for the *gag* gene, *gag-pol*, *env*, *vif*, *vpr*, *vpu*, *tat*, *rev*, and *nef* (Figure 1.1 A). *Env* produces the gp160 transmembrane protein which is cleaved into gp120 and gp41 in the Golgi complex⁴⁰. The *gag* gene is cleaved into the matrix protein (MA, p17), the capsid protein (CA, p24), the nucleocapsid (NC, p7), p6, and two spacer peptides SP1 and SP2 when the virion matures⁴¹⁻⁴⁴. The *gag-pol* gene created by a ribosome slippage encodes for the above-mentioned *gag* proteins but instead of SP2, protease, reverse transcriptase and integrase are also produced^{43,44}. *Vif*, *Vpr*, *Vpu* and *Nef* are generally considered accessory proteins since they are not strictly essential to produce a virion. They do however contribute greatly to the success of the nascent viral particle^{45,46}. The viral genome and replication cycle for HIV are summarized in Figure 1.1 A and B respectively.

Person to person transmission of HIV occurs through the exchange of bodily fluids with infected individuals. This can include the exchange of blood, breast milk, semen, and

vaginal secretions, and typically requires the overcoming of a physical barrier such as the epithelial tissue⁴⁷⁻⁵³. During sexual transmission, the mucosal epithelium provides a substantial barrier to the virus and microtears are required for the virus to enter the host^{47,48,54,55}. The initial virion able to overcome this physical barrier is termed the transmission founder (TF) virus⁵⁶⁻⁵⁹. The first cells to encounter HIV in both the female genital tract and the inner foreskin are site specific dendritic cells, epidermal Langerhans cells (eLCs)⁶⁰. These cells then carry the infection to nearby CD4+ T cells either in the submucosa or nearby lymph nodes where the infection can be disseminated⁵⁶. Viral spread to the gut associated lymphoid tissue (GALT) is essential for the establishment of infection. The lymphoid cells in this region of the body are more abundant than anywhere else and are generally in a low state of activation, making them ideal candidates for infection⁶⁹. Although the infection is usually introduced into the body from elsewhere, such as the vaginal mucosa or the peripheral blood, it only establishes a secure foothold once it reaches the GALT and has access to this rich proinflammatory environment with IL2, IL6, and TNF- α which are considered stimulatory cytokines^{70,71}. Dissemination of HIV to immunologically protected sites such as the brain form long lasting viral reservoirs^{67,68}.

Expression of the receptor CD4 and coreceptor CCR5 and CXCR4 are usually required although cells not expressing these receptors such as kidney epithelial cells and astrocytes can be infected via endocytosis or cell-to-cell transfer bypassing the membrane fusion stage of entry^{61-63, 66}. The main targets of HIV, T cells, monocytes, immature dendritic cells, and macrophages all express the CD4 receptor, albeit at varying levels^{61,62,64,65}. The HIV infection cycle is divided into two stages: the early stages which include attachment, fusion and entry, uncoating, nuclear entry, and integration; and the late stages which include viral transcription, nuclear export, translation, assembly, budding and maturation (Figure 1.1 B).

Attachment and fusion of the virion occurs at the cell membrane; however, these initiating events can vary by cell type as well as the stage of infection. HIV attachment

can occur via interaction with integrins, pattern recognition receptors such as dendritic cell-specific intercellular adhesion, molecular 3-grabbing non-integrin (DC-SIGN) or nonspecific interactions with negatively charged cell-surface heparan sulfate proteoglycans^{72,73}. Langerhans cells express a C-type lectin called langerin which is known to bind HIV⁶⁸ whereas lymphocytes express integrin $\alpha 4\beta 7$ ⁷¹. Although these attachment factors are helpful and likely aid in stabilizing the virion on the plasma membrane to interact with CD4 and the coreceptor they are not strictly essential for infection to occur^{71,73}.

In cell-free infection, viral particles are released from the cell and proceed to infect non-adjacent cells, usually through fusion with the plasma membrane^{74,75}. The envelope protein which studs the surface of the virion is made up of a heterodimer of gp120 and the transmembrane gp41. These heterodimers form a trimer where the gp120 proteins are facing outwards like an umbrella and shields the transmembrane gp41 proteins⁷⁶⁻⁷⁹. The gp120 trimer interacts with the CD4 receptor and with the aid of a coreceptor further conformational changes take place which allow for the insertion of the gp41 section of the envelope into the cell membrane and brings them in close proximity to mix with the plasma membrane of the target cell. The transmitter founder virus usually utilizes the CCR5 receptor and viruses utilizing the CXCR4 receptor usually emerge later during the progression of the infection⁷⁰. There are other coreceptors which have been shown to interact with the envelope protein in vitro and these alternate coreceptors could account for the ability of HIV to infect almost all cell types^{70,73,76,80,81}. The binding of multiple CD4 receptors to the envelope can speed up the process of opening the gp120 trimer and exposing the gp41 peptides for fusion. A more efficient form of viral dissemination is cell-to-cell transmission whereby a virological synapse, similar to an immunological synapse, is formed to connect two susceptible cells and allow the transmission of virions⁷⁵. Cell-to-cell contact is facilitated by LFA-1 and ICAM-1 receptors on the cell surface maintaining the donor and receiver cell in close contact during the transmission^{73,82,83}. This attachment causes additional signal transduction and biochemical changes within both the donor and the receiver cells which influence viral

spread and pathogenesis^{74,75}. Both cell-free and cell-to-cell transfer result in the shedding of the viral membrane and release of the viral core into the cytoplasmic milieu.

Following the release of the capsid into the cell, the reverse transcription and uncoating steps are initiated in the cytoplasm. Uncoating is thought to aid in the transport of the HIV genetic material to the nuclear pore where it can enter the nucleus and integrate into the genome. The capsid core is transported along microtubules towards the nucleus^{87,90-93}. This movement is aided by the adaptor protein FEZ1 which accommodates the attachment of the capsid molecules to the motor protein Kinesin-1⁹⁴. Although the mechanism of motor movement is incompletely understood it has been demonstrated by several groups that binding to both the dynein and kinesin motors is required for the movement of the core toward the nucleus⁹⁴. Depleting the cell of either motor protein results in accumulation of particles at the plasma membrane and diffusely throughout the cytoplasm⁹⁵. The timing of viral core uncoating is essential for the infectivity of the virus, whereby early uncoating of viral particles can lead to the degradation of the pre-integration complex by the proteasome as well as detection of viral components by the surveillance molecules such as cGAS^{96,97}. Imaging studies have suggested that uncoating at or near the nuclear pore is important for the import of the pre-integration complex into the nucleus. Viral docking occurs through association with nucleoporin 358 (NUP358)^{91,96,97}. This, in concert with binding of the capsid to NUP153 and CPSF6, are important interaction for the import of the pre-integration complex into the nucleus⁹⁷.

The reverse transcription complex which is thought to form shortly after entry into the cytoplasm consist of matrix proteins, capsid proteins, reverse transcriptase, integrase, nucleocapsid, Vif, Tat, Nef, Vpr and protease⁸⁴. Although it is unclear if these are coincidental associations or whether they have a positive effect on the reverse transcription process⁸⁵. The nucleocapsid protein is believed to act as a chaperone and help in the reverse transcription of the RNA. It arranges nucleic acids in the most thermodynamically stable position and aids in the annealing of the tRNA which serves as the primer in the DNA synthesis^{86,87}. The reverse transcription process can even occur in

vitro with just the reverse transcriptase (RT), dNTPs, and a template^{84,88}. RT has two enzymatic activities: 1) the DNA polymerase function which creates DNA using either RNA or DNA as the template and 2) the RNase H activity which degrades the RNA template only when it is complexed with a DNA strand⁸⁸. The steps of reverse transcription convert a positive sense single-stranded RNA genome into a double-stranded DNA genome. A tRNA primer base binds to the primer binding site near the 5' end of the viral RNA. This initiates reverse transcription to generate the minus strand of viral DNA (vDNA). The RNase H active site of the RT degrades the viral (vRNA) releasing the newly synthesized vDNA strand. This strand folds back and binds to the 3' R region. HIV-1 has packaged two copies of the viral RNA and this DNA fragment can bind to the 3' region of either vRNA strand allowing for the synthesis of the rest of the vRNA genome⁸⁴. As the minus-strand of DNA continues to be synthesized the RNase H continues to degrade the viral RNA with the exception of two small regions called the polypurine tract (ppt) which are located near the 3' region and near the middle of the genome. These ppts act as primers for the initiation of the transcription of the positive-sense DNA strand^{84,89}. The plus-strand synthesis can commence from either ppt and continues until the tRNA primer set. This is then removed by the RNase H activity which frees the plus-stranded DNA for transfer to the 5' end of the minus strand, where extension of the plus-strand leads to the completion of the double-stranded viral DNA. The reverse transcribed genome in complex with integrase, some capsid proteins and cellular factors is named the pre-integration complex (PIC)⁹⁰.

There has been continuous debate about where and how reverse transcription occurs and how this process is linked to the uncoating of the capsid to expose the pre-integration complex of viral DNA for binding into the host DNA. The model of reverse transcription, uncoating and integration which is beginning to emerge consists of the initiation of reverse transcription in the cytoplasm as the core is moving towards the nuclear membrane⁹⁶. Some groups propose that the uncoating of the virus occurs at the nuclear pore where most of the capsid is shed, however a small amount of capsid travels with the viral replication complex (VRC) into the nucleus⁹⁶. In the nucleus, in association with

CPSF6 the VRC is guided towards nuclear speckles where it integrates within nuclear speckle associated genomic domains (SPADs)⁹⁸. A separate theory proposes, that shedding of the capsid does not occur in the cytoplasm or nuclear pore but that a nearly intact capsid enters the nucleus where it completes the reverse transcription steps and proceeds to uncoat near the integration sites approximately 1.5 μm away from the nuclear envelope⁹⁹. Both studies did find that the host cofactor CPSF6 is important for the facilitation of nuclear entry and post entry events^{98,99}. It is clear that there is a complex interplay between the entry of capsid into the nucleus and the direction of PIC into the target site for integration which requires further clarification. The import of the capsid and the integration of the viral genome involves the aid of several cell host proteins such as CypA, RANBP2 (also known as NUP358), CPSF6, TNPO3, NUP153. CPSF6 and NUP153 are involved in both the import of the PIC into the nucleus as well as the selection of integration sites on the host genome^{98,99}. Altering the interaction of the capsid with these factors influences not only the entry route of HIV into the nucleus but also the site of integration into lamina-associated DNA (LADs)^{90,99,100}.

Upon entry into the nucleus, integrase processes the 3' end of the HIV genome by removing two nucleotides from each end and turning the blunt ends of the genome into reactive ends¹⁰⁰. The viral DNA docks onto the target site on the host genome and forms a target capture complex where the exposed 3' ends of the viral DNA are used as nucleophiles to attack the target DNA at the major groove. Complimentary strands then join with the 5' end of the host genome and host DNA repair machinery join the gaps creating a 5 bp extension onto the integrated provirus¹⁰⁰. The selection of integration site can determine how actively the viral genome will be transcribed or whether latency will be established¹⁰¹⁻¹⁰³. Determinants of HIV latency are a highly active area of research and evidence suggests that it may be influenced by both the site of integration and cellular factors. Generally, HIV has been shown to integrate into highly transcribed genes. This preference may be influenced by the cellular factor LEDGF as its depletion leads to a shift away from active genes¹⁰⁴. Additionally, integration seems to favor the nuclear periphery and open chromatin, and disfavors LADs, heterochromatin condensed regions

and centrally located transcriptionally active regions. Non-canonical B-form DNA has also been shown to influence integration at the nucleotide level^{101,105,106}.

Once the provirus is integrated into the host DNA, transcription can commence. The initial activation of the provirus largely depends on the state of the host microenvironment including the availability of the transcriptional cofactors and the state of activation of the cell¹⁰⁵. The availability and abundance of host transcription factors affect the ability of the virus to enter the host phase and subsequently the highly active viral phase that follows¹⁰⁷⁻¹¹⁰. This availability also contributes to the heterogeneity in the transcriptional activation and latency observed both in cell culture and in vivo¹¹¹. The RNA produced in the latent state is at low levels and the transcripts are short and immature¹¹⁰. Activation of the CD4+ T cell and NF- κ B leads to a state where the early HIV genes, *tat*, *nef*, and *rev* are expressed¹⁰⁵. The proviral promoter has a binding site for both NF- κ B and NFAT either of which could initiate active transcription of these viral early genes^{109,110,112}. The transcriptional circuit of HIV is dependent on the Trans activator of transcription (Tat) protein creating a positive feed-back loop and only jumps into high gear once the Tat protein is transcribed and translated¹¹². The LTR contains the core promoter elements which include three tandem SP1 binding sites, a TATA box, and a highly active initiator sequence^{109,110,112}.

Tat expression leads to a 100-fold increase in transcription of HIV genes and production of full-length RNA transcripts^{109,110}. Tat binds to the Trans Activating Response (TAR) element, an RNA stem-loop structure located in the first 59 nucleotides at the 5' LTR. This leads to the recruitment of P-TEFb (positive transcription elongation factor B), the phosphorylation of RNA polymerase II, and increased transcription of viral mRNA¹⁰⁸. In the absence of Tat, the low-level boost of transcription provided by cellular activation is short-lived and leads to the production of a small amount of viral transcripts. During the host phase of the transcriptional activation the host protein KAP1/TRIM28 seems to be important for the initiation of transcription. However, upon Tat expression KAP1 seems to be dispensable for the recruitment of CDK9 and transcriptional activation¹¹⁰. Since the

proviral DNA contains only one transcriptional start site alternate splicing is required to generate the large spectrum of viral mRNAs produced.

Typical conversion of pre-RNA into mRNA involves the removal of introns, addition of a 5' cap and polyadenylation at the 3' end^{114,115}. The same holds true of HIV mRNA. HIV RNA has 5 exons which splice together to form the various viral mRNAs. As a rule, the first and last exons are always used^{113,115}. Three forms of RNA are translated from the viral DNA: 1) a full-length, unspliced, ~ 9 kB mRNA from which Gag and Gag-Pol are translated; 2) a singly or partially spliced, ~4 kB mRNA from which gp160 (Env), Vif, Vpu and Vpr are translated; and 3) a fully spliced mRNA from which Nef, Tat, and Rev are translated^{113,115,116}. Two copies of the unspliced, full-length RNA are also incorporated into the new viral particles¹¹⁷. The tendency of the cell is to splice pre-RNA and the default state for HIV RNA is for full splicing to occur. Thus, the 2 Kb multi-spliced transcript of *rev*, *tat* and *nef* are the first produced and they are exported into the cytoplasm through the NXF1 nuclear export pathway similarly to the majority of the host mRNAs^{107,113,118}. There, *rev* and *tat* are translated and shuttled back into the nucleus via the nuclear localization signal^{107,113}. As mentioned previously, Tat production and nuclear import is essential for increasing the rate of transcription whereas Rev is essential for the export of unspliced and partially spliced viral mRNA from the nucleus. Partial and unspliced mRNAs required virus specific suppression of splicing by overriding the cellular rules to retain introns¹¹⁵. Normally, the export of unspliced and intron retained RNA is blocked at the nuclear pore thus the unspliced and partially spliced viral mRNA requires the aid of newly synthesized Rev to mediate export through the CRM1 pathway^{107,119}. Intron containing RNA is unstable and quickly degraded in the nucleus, Rev multimerizes around the viral mRNA to protect it from cellular degradation¹¹³. Expression of Rev leads to decreased levels of fully spliced viral mRNA whereas an increase in fully spliced mRNA is observed when Rev expression is decreased^{115,120}. Upon nuclear import, Rev binds to the rev response element (RRE), a short loop on the 5' end of the transcript. This leads to a conformational change and recruitment of other Rev proteins for multimerization¹⁰⁷. Rev contains a leucine rich nuclear export signal at the

disordered C-terminal domain which forms a complex with RanGTP and CRM1 (also known as exportin1 or XPO1) to shuttle through the nuclear pore complex into the cytoplasm where it disassembles when RanGTP is hydrolyzed into RanGDP^{107,121}.

In the cytoplasm, the cellular translation machinery is used to generate viral proteins from both the spliced and unspliced viral mRNAs. The 5' end of the unspliced mRNA from which Gag and Gag-Pol are produced contains several structural elements such as the TAR element, the primer binding site, the dimer initiation site, and packaging signal, which, while essential to replication hinder the translation initiation^{108,113,122,123}.

Recruitment of cellular proteins such as the La protein, TAR RNA-binding protein (TRBP) and Staufen1 aid in overcoming the translation barriers created by these secondary RNA structures^{124–127}. While other cellular factors such as cap-binding complex subunit CBP80 and DEAD-box RNA helicases such as eIF4AI and DDX3 cooperate with Rev to recruit the ribosomal subunits for the initiation of the translation of the unspliced and partially spliced mRNAs^{107,128,129}. Unspliced mRNA translation produces the Gag proteins while a -1 ribosome frameshift governed by a 6U slippery site, and a downstream stem-loop structure produces the Gag-Pol protein^{130,131}. Maintenance of a ratio between the 55 kD Gag (Pr55) and the 160 kD Gag-Pol production at 2% to 10% Gag-Pol is important for the assembly of the virion and may be modulated by the availability of Leu tRNA¹³¹.

Gag is the master orchestrator of the viral particle assembly and Gag containing virus-like particles (VLP) are formed in the absence of any other viral proteins^{42,79,132}. Gag and Gag-Pol are translated in the cytoplasm on free ribosomes⁴¹. The Gag protein consists of a matrix (MA) domain at the N-terminus, followed by the capsid domain (CA), nucleocapsid domain flanked by two spacer region SP1 at the n-terminus and SP2 at the c-terminus, and lastly the p6 domain at the c-terminus of Gag^{41,93,133–135}. Although there is some uncertainty about which step comes first, multimerization, RNA binding, or membrane targeting, the end result is that same, assembly of Gag/Gag-Pol, and viral RNA at the plasma membrane where the incorporation of Env and budding occur. The

myristalated matrix domain targets the Gag particles to the inter leaflet of the plasma membrane, the capsid domain mediates Gag-Gag interactions and multimerization into hexamers, the nucleocapsid domain binds two copies of the unspliced viral RNA to be incorporated into the nascent viral particle and the p6 domain recruits the cellular ESCRT machinery to complete membrane cession and release from the cell^{42,93}.

A myristate moiety is post-translationally attached to the N-terminal of the matrix domain, a modification which together with a basic patch of amino acids targets Gag molecules for transport to the plasma membrane^{41,93,134,136}. Elimination of this myristylation changes the destination of the Gag molecules from the plasma membrane to a more diffuse cytoplasmic localization^{136,137}. Capsid-capsid interactions are important for the multimerization of the Gag molecules into hexameric sheets as well as the recruitment of essential cell factor cyclophilin A (CypA). CypA incorporation into the viral particle can drastically alter infectivity of the viral particle^{91,138}. It is important for protection from cellular restriction factor TRIM5 α as well as for successful and timely uncoating upon entry in the cell^{138,139}. The 5' end of the unspliced HIV genome contains a highly structured stretch of 150 to 200 bp which encode the packaging signal (ψ or ψ). This region contains a nucleocapsid (NC) binding site on stem loop three as well as a dimer initiation signal (DIS) on stem loop one. Packaging of RNA requires an intact ψ packaging element as well as parts of the RRE and gag sequence for efficient packaging although in the absence of RNA containing these elements, spliced HIV RNAs will be packaged and, in their absence, cellular RNAs can get packaged into the particles¹⁴⁰. Interestingly, although the pool of unspliced RNA is both translated into the Gag/ Gag-Pol proteins and incorporated into nascent viral particles, stable RNA-Gag complexes near the plasma membrane are only seen with non-translating viral RNA. The encapsidation of two copies of viral RNA is important for viral recombination as the RT switches between the two templates during the reverse transcription process^{41,88,89,141}.

Binding of the nucleocapsid domain of Gag to the ψ element is thought to begin the assembly of the immature particle providing a scaffold for the multimerization of the Gag

lattice at the plasma membrane^{93,142}. Through actively remodeling the viral assembly HIV acquires a unique membrane protein composition. As Gag multimerizes at the inner leaflet of the plasma membrane phosphatidylinositol 4,5-bisphosphate (PIP₂) molecules, through interactions with the highly basic region on MA are incorporated into the assembly site¹⁴³. This kicks off the process of remodeling through trans bilayer coupling and selection of GPI anchored proteins into the virion. As the membrane acquires high curvature dual membrane anchors are recruited to the viral assembly site¹⁴³. It was long thought that Gag multimerization alone provided the required force to bend the plasma membrane for particle formation, however, more recent studies have discovered that BAR domain-containing proteins such as IRSp53 and angiomin (AMOT) may be required to aid bending the membrane¹⁴⁴⁻¹⁴⁷.

Budding and release of the virions is largely dependent on the cellular endosomal sorting complex required for transport (ESCRT) complex^{93,148}. Made up of more than 30 proteins the human ESCRT machinery performs a complex dance regulated by ubiquitin and other regulatory machinery to coordinate the remodeling of the membrane during intraluminal vesicle. This is choreographed by the p6 domain of Gag which contains the PTAP and the YPXL late domain^{41,149,150}. TSG101 subunit of the ESCRT-I complex binds to the PTAP domain of Gag to recruit the ESCRT-III proteins CHMP2 and CHMP4 which in conjunction with VSP4 mediate membrane fission through polymerization in a dome structure which pulls together the two sides of the membrane neck^{43,147,151}. Similarly, the YPXL domain is the binding site for the ALIX protein which in turn recruits CHMP2 and CHMP4 to complete membrane fission. In addition to aiding in membrane scission VSP4 releases the ESCRT complex back into the cytoplasm⁴³. Ubiquitination of Gag by the ubiquitin ligase NEDD4L can rescue the budding deficiencies of Gag which lacks TSG101 and ALIX binding site^{41,151}. In addition to its contribution in budding the p6 domain is essential for the recruitment of Vpr into the nascent viral particles^{41,152}. The functional consequence of Vpr recruitment into viral particles is uncertain but recent studies have suggested that Vpr is dissociated quickly upon cell entry and any residual molecules are associated with the capsid suggesting a role in early infection¹⁵².

The Env glycoprotein precursor (gp160) contains an ER signaling sequence targeting for translation on the rough endoplasmic reticulum⁷⁹. A hydrophobic membrane anchor at the transmembrane domain of gp160 prevents it from being released into the ER lumen^{79,153}. Gp160 undergoes co-translational glycosylation with both *N*-linked and *O*-linked oligosaccharide sidechains. In the ER, gp160 forms trimers which are thought to facilitate the trafficking to the Golgi complex where it acquires extensive sidechain modifications. There, it is proteolytically cleaved by furin or furin-like proteases to produce the surface glycoprotein (SU) gp120 and the transmembrane glycoprotein (TM) gp41, which remain noncovalently associated. The proteolytic cleavage of gp160 is a process required to activate the fusogenic abilities of Env which are essential for entry into the cell and infectivity. The trimeric complexes of gp120 and gp41 is trafficked to the plasma membrane where it is quickly recycled back into the cell via clathrin mediated endocytosis⁷⁹. The weak noncovalent association between the gp120 and the gp41 subunits often results in shedding of gp120 which together with the endocytosis maintains a relatively low concentration of Env at the plasma membrane and in incorporated particles. There are four, not mutually exclusive, models for how Env is incorporated into viral particles: 1) passive incorporation whereby Env is incorporated into the virion simply due to it being on the cell membrane 2) direct Gag-Env interaction model whereby a direct interaction of the matrix domain and the cytoplasmic tail of Env incorporated it into the virion 3) The Gag-Env co-targeting model where Env incorporation is due to targeting of both Env and Gag to specific plasma membrane microdomains 4) indirect Gag-Env interaction model where a host protein acts as an adaptor molecule linking the cytoplasmic tail of Env with the matrix domain in Gag^{79,154}. While some evidence exists for all these models, recent studies utilizing matrix trimerization mutants found that Env incorporation was dependent on the formation of matrix trimers and an intact cytoplasmic tail¹⁵⁵.

The last step in the infection cycle of HIV is maturation of the released particles. In this critical step the viral protease cleaves Gag and Gag-Pol at multiple positions leading to structural rearrangements which prepare the virus for entry into the target cell. The viral

protease is incorporated into the virion as part of the Gag-Pol precursor and during or slightly after budding initiates a highly ordered sequential cleaving cascade^{44,130,134}. Protease processing of Gag and Gag-Pol results in production of the matrix, capsid, nucleocapsid, p6, protease, reverse transcriptase, and integrase. The matrix proteins remain bound to the viral envelope while the capsid proteins arrange into a cone shape which surrounds the condensed ribonucleoprotein complex (RNP) formed by the nucleocapsid and RNA¹⁵⁶. The first cleavage occurs between SP1 and NC domain, followed by MA-CA and SP2-p6 junction, NC-SP2 site, and finally between CA and SP1. The last cleavage liberates the capsid protein to assemble into the conical viral core^{43,135}. The cleavage of the CA-SP1 site is particularly important as uncleaved capsid molecules exert a dominant negative effect and severely reduce viral infectivity^{157,158}. Consistent with its importance in HIV infectivity, virion maturation has been the successful target of a class of antiretroviral drugs called protease inhibitors.

Studying the replication mechanisms of HIV is essential to the development of antiviral drugs, especially since the development of a vaccine has thus far been unsuccessful. Antiretroviral drugs, on the other hand, are currently the only available treatment for HIV infection. The development of new drugs is required to combat the drug resistant strains which have evolved and keep the infection at bay.

A HIV-1 genome

HIV-1 virion

B

Figure 1.1: HIV-1 genome and replication cycle.

A) Top panel, HIV genome. The HIV genes are flanked by a 5' and a 3' long terminal repeat region. The 5' LTR is followed by the psi (ψ) packaging signal, *gag* and *gag-pol*, *vif*, *vpr*, *vpu*, *env* and *nef*. The *rev* and *tat* genes are produced by alternate splicing. Three forms of RNA are translated from the viral DNA: 1) a full-length, unspliced, ~9 kB mRNA from which Gag and Gag-Pol are translated; 2) a singly or partially spliced, ~4 kB mRNA from which gp160 (Env), Vif, Vpu and Vpr are translated; and 3) a fully spliced mRNA from which Nef, Tat, and Rev are translated. Bottom panel, cartoon representation of the mature HIV particle. **B)** HIV replication cycle. 1) The gp120 trimer interacts with the CD4 receptor and with the aid of a coreceptor (CXCR4 or CCR5) further conformational changes take place which allow for fusion of the virion with the plasma membrane. 2) The viral membrane is shed, and the viral core is released into the cytoplasmic milieu. 3) Uncoating aids in the transport of the HIV genetic material to the nuclear pores where it can enter the nucleus and integrate into the genome. 4) The steps of reverse transcription convert a positive sense single-stranded RNA genome into a double-stranded DNA genome. The reverse transcribed genome in complex with integrase, some capsid proteins and cellular factors form the pre-integration complex (PIC). 5) Viral docking at the nuclear membrane occurs through association with nucleoporin 358 (NUP358). This, in concert with binding of the capsid to NUP153 and CPSF6 import the pre-integration complex into the nucleus. 6) In the nucleus, in association with CPSF6 the viral replication complex is guided towards nuclear speckles where it integrates within nuclear speckle associated genomic domains (SPADs). The selection of integration site can determine how actively the viral genome will be transcribed or whether latency will be established. 7) Activation of cells initiates the transcription of the early HIV genes *tat*, *rev*, and *nef* which kicks into gear the transcription of other HIV genes and production of full-length RNA transcripts. Alternate splicing generates the large spectrum of viral mRNAs produced. 8) Unspliced viral RNAs exit the nucleus via the CRM1 pathway with the aid of Rev while fully spliced viral RNAs exit the nucleus via the NXF1 pathway. 9) both spliced and unspliced viral RNAs are translated into viral proteins in the cytoplasm using cellular translation machinery. 10) Gag is the master orchestrator of the viral particle assembly coordinating

multimerization, RNA binding, and membrane targeting. 11) Virion budding is dependent on the cellular endosomal sorting complex required for transport (ESCRT) complex. The p6 domain of Gag recruits various members of the ESCRT complex to budding and scission of the membrane. 12) In the maturation step the viral protease cleaves Gag and Gag-Pol at multiple positions leading to structural rearrangements which prepare the virus for entry into the target cell.

1.2.2 Ebolavirus Replication Cycle

Predominantly filamentous shaped, Ebolaviruses are membrane bound and contain a 19kB non segmented, negative sense, linear RNA^{3,93}. This codes for the structural matrix protein VP40 which can assemble into filamentous particles in the absence of any other viral proteins^{159–161}. The EBOV genome also encodes for *GP* the glycoprotein GP_{1,2} as well as the secreted glycoproteins, *NP* the nucleocapsid protein, *VP35* the polymerase cofactor, *VP30* the transcriptional activator, *VP24* the RNA complex-associated protein, and *L* the large protein RNA-directed RNA polymerase (Figure 1.2 A)^{3,161}.

Most EBOV outbreaks begin with a single spillover event into the human population from an unknown reservoir by unknown means, although there is some evidence for bats being the reservoir host and non-human primates acting as an intermediary species^{3,162–165}. Human-to-human transmission can occur through sexual contact, although direct contact with infected biological materials or exposure to contaminated non biological materials such as through an open wound or contact with mucosal membranes is considered the most frequent mode of transmission^{3,4,166}.

EBOV cell tropism is determined by the glycoprotein GP_{1,2} and the cellular attachment factor NPC intracellular cholesterol transporter 1 (NPC1, also known as Niemann–Pick C1 protein) receptor. The primary targets of infection are mononuclear phagocytes and dendritic cells which upon infection disseminate the virus e regional lymph nodes and to the liver, spleen, and kidney^{167–170}. EBOV infection of these organs results in focal necroses and inflammation which leads to multi-organ dysfunction and death^{4,166,170,171}.

Although EBOV impairs the function of immune cells preventing them from clearing the infection, they are able to secrete cytokines and chemokines resulting in enhanced immune activation resembling septic shock^{4,172,173}. Ebola GP activates monocyte-derived macrophages through TLR4 and induces NF- κ B as well as IRF3 activation-based production of cytokines and chemokines. This results in increased expression of interleukins IL-1 β , IL-6 and IL-8, as well as tumor necrosis factor (TNF)^{3,174}. It also strongly induces production of IFN beta and the interferon response¹⁷². This immune activation results in the recruitment of susceptible immune cells and the failure of the endothelial barrier. Additionally, natural killer cells (NK cells) and T cells undergo apoptosis, despite remaining uninfected, further impairing the ability of the immune system to overcome the disease^{3,169}.

At the molecular level, EBOV replication cycle begins with attachment to the host cell membrane (Figure 1.2 B). Attachment can be mediated by several host surface proteins including C-type lectin, DC-SIGN and L-SIGN, and integrins such as $\alpha_5\beta_1$ integrin, as well as TIM-1, TIM-4 and the TAM kinases TYRO3, AXL, and MERTK¹⁷⁵⁻¹⁷⁷. There are somewhat conflicting reports about the strict requirement of any of these receptors for entry since not all are present in the various cell types that EBOV infects. The most likely scenario is that these receptors as well as some yet to be identified act as attachment factors which mediate macropinocytosis of the virion through pathways similar to those used for apoptotic cells¹⁷⁸⁻¹⁸⁵. Conflicting reports suggest that macropinocytosis occurs in either a clathrin-dependent or a caveolin-dependent manner, however, most agree that remodeling of the actin cytoskeleton is essential for entry¹⁸⁶⁻¹⁸⁸. Particularly PI3K – AKT – RAC1 axes is important for the maturation of the endosomal compartments containing EBOV, knocking down any of these components resulted in the intracellular accumulation of EBOV in these compartments and inhibited entry^{188, 189}.

Once the virion is macropinocytosed the vesicle proceeds to mature into an early endosome and then into Rab7-positive late endosome/ lysosome compartments¹⁸⁸. With the increase in acidity the cathepsin molecules are activated. The GP1 subunit gets

proteolytically processed in the late endosome by cysteine proteases Cathepsins B and L removing the mucin like domain and the glycan cap^{177,190,194}. This cleavage exposes the receptor binding site of the molecule and primes GP (now GPCL) for the interaction with NPC1. It is well documented that NPC1 is an essential mediator of entry into the cell. There is unequivocal agreement that release of the capsid into the cytoplasm occurs following the interaction of the GP1 subunit with NPC1^{177,190-193}. Binding of GP to the NPC1 receptor trigger conformational changes which are poorly understood to create a fusion pore and facilitating the release of the nucleocapsid into the cytoplasm where the replication of the genome can occur^{176,178,183,193,195,196}

The fate of VP40 following release into the cytoplasm is unknown however dissociation of VP24 from the incoming nucleocapsid facilitates the relaxation of the rigid structure allowing for transcription and genomic replication to occur⁴. Primary transcription commences about two to four hours post infection and utilizes the original viral genome and proteins. Transcription occurs within the ribonucleoprotein complex which contains NP, VP30, VP35, and L. EBOV mRNAs are sequentially transcribed from the 3' end to the 5' end with conventional start and stop codons preceding and trailing each gene^{4,197}. Between the end of one gene and the start of the next there is a short intragenic region of about 5 nucleotides except for between *vp30* and *vp24* where there is an intragenic region of about 143 nucleotides. The transcription process is not perfect and at times, the polymerase falls off after finishing the transcription of a gene. When this occurs, it cannot pick up where it left off and needs to start the transcription process from the beginning, creating a gradient of transcribed genes and proteins with NP being the most abundant followed by VP35, VP40, GP, VP30, VP24, and L being the least abundant^{3,7,8,198}. L acts as both a polymerase as well as a having guanyltransferase and methyltransferase activities to cap the 5' of the nascent viral mRNAs to create translatable viral mRNAs^{7,198}. Following transcription, the nascent mRNAs, except for GP, are translated by the free ribosomal machinery in the cytoplasm¹⁹⁸. When a certain level of NP protein is reached, it localizes near the ER forming the inclusion bodies which are a hallmark of EBOV infection^{199,200}. Usually, they appear in cells about 10 hours post infection and are the

site of nascent RNA synthesis. Inclusion bodies contain NP, VP35, VP30, VP24, VP40 and L although only NP is required for their formation^{200,201}. How inclusion bodies are formed by EBOV remains unknown, but they are thought to originate through lipid phase separation. Once formed, inclusion bodies become the site of secondary translation, genome replication and nucleocapsid assembly. As more proteins are translated smaller inclusion bodies merge to form larger ones^{200–202}.

The only EBOV mRNA subjected to transcriptional editing is *GP*. Three different forms of glycoprotein transcripts are generated by L due to transcriptional stuttering at a polyuridine region. *pre-sGP*, *pre-GP*, and *pre-ssGP* are translated into pre-sGP pre-GP₀ and pre-ssGP, respectively in the ER^{161,173,203}. About 70% of the transcriptional GP products form a dimer at a unique C-terminus and are secreted (sGP); approximately 25% are comprised of the GP₀ gene product which following translation gets cleaved to form the GP_{1,2} protein, and lastly, 5% of the transcripts form a small, secreted form of the glycoprotein (ssGP)^{173,204}. sGP is the main transcriptional product and it is proteolytically cleaved and glycosylated as it moves through the classic secretory pathway to be discharged in the extracellular milieu^{161,173,205,206}. Retention of sGP in the cell can be highly toxic and has been implicated in acting as a decoy to evade antibody immunity, impairing the chemotaxis of macrophages, and inhibiting the production of proinflammatory cytokines^{173,207,208}. The proteolytic cleavage of sGP results in the formation of a small 40 aa protein called the delta (Δ) peptide²⁰⁹. This also follows the secretory pathway but is retained in the cell for longer than sGP. Possible functions of this residual protein are inhibition of filovirus to prevent superinfection and acting as a membrane damaging viroporin^{173,206,210}. The GP₀ gene product is also translated in the ER where it assembles into trimers and follows the classical secretory pathway to the plasma membrane^{161,207}. Each GP₀ subunit is then post translationally cleaved by the Golgi endoprotease furin to yield disulfide linked GP1 (~55 kDa) and GP2 (~20 kDa) subunits. The final GP assembly, which is an ~450 kDa trimer of GP1,2 heterodimers, is then displayed on the surface of mature EBOV virions and is essential for viral entry^{161,173,204,211}. GP1 contains the receptor-binding site and regulates the triggering of

the membrane fusion machinery in the GP2 subunit^{173,194}. Expression of GP is highly regulated and large amounts of GP_{1,2} are cleaved from the cell surface by the cellular metalloprotease tumor necrosis factor alpha-converting enzyme (TACE) and shed from the cells²¹². Like sGP, these shed trimers act as decoy from the immune system and sequester antibodies to prevent their binding to the viral particles^{208,213}. Additionally, it reduces the cellular toxicity imposed by GP and causes immune activation of monocytes²¹⁴. The last transcription product ssGP is created by a + 2-shift reading frame of the GP gene²⁰⁴. Similar to sGP it is heavily glycosylated and forms a homodimer however its function is thus far unknown^{161,173}.

The inclusion bodies are the site of secondary translation for all the other EBOV proteins as well as genome replication and nucleocapsid assembly²¹⁵. It is unclear how the transcription and genome replication stage of the viral replication cycle are separated in space and time however they are distinguished by the presence of the transcription initiation factor VP30²¹⁵. Transcription of proteins requires the presence of non-phosphorylated VP30 which helps initiate the transcription process²¹⁶. Upon phosphorylation, due to interrupted interaction to VP35, VP30 dissociates from the polymerase complex and its association with NP is strengthened. Enhanced binding to NP allows for its incorporation into the nascent viral particle, a step which is critical for the initiation of primary transcription upon entry into a new host cell²¹⁶⁻²¹⁸.

During the translation stage of the replication cycle VP35 is bound to NP to prevent oligomerization. When the switch from translation to genomic replication occurs and viral RNA is available NP molecules bind to it displacing the VP35-NP interaction and allowing for the multimerization of NP around the nascent viral RNA^{200,219-223}. The EBOV genome contains a bipartite motif within the 3' leader region and the first gene (NP). Access to this promoter instructs the viral polymerase to synthesize a full-length antisense genome^{216,217}. This RNA template is uncapped and non-polyadenylated and is associated with NP^{223,224}. The 5' end of the genome is composed of a short non transcribed region which is important for replication, transcription initiation, and

encapsidation. The antisense genome (antigenome) serves as a template from which the future genomes are synthesized^{4,197}. The replication promoter of the antigenome resides in the complementary promoter region and directs the viral polymerase to begin synthesis of genomic RNA. VP24 and VP35 then come in to complete the condensation of the nucleocapsid structure²²⁴. Encapsidation by multimerization of NP and VP35 of the viral RNA is cooperative with the extension of the genome^{224,225}. Thus, the genome gets encapsidated as soon as it is replicated allowing for a method of protection from degradation²²⁶.

The loose encapsidation of the genome following replication is the first step in the particle formation. This is accomplished by NP, VP35, and L which form a left-handed helical structure^{215,216,224,227,228}. Then VP30 binds to the nucleocapsid and determines if the complex will function as a replicase or transcriptase depending on whether VP30 is phosphorylated or not. VP24 binds to the nucleocapsid complex locking it in place and preparing it for transport to the budding site²²⁴. The presence of VP24 is important for the stabilization and condensation of the nascent nucleocapsid however timing and amount is essential. If there is too much VP24 expressed this can lead to premature capsid condensation and inhibit the movement of L polymerase¹⁹⁷.

Since the synthesis and assembly of the nucleocapsid occurs in the perinuclear region of the cytoplasm in the inclusion bodies this nucleocapsid complex then needs to be transported to the plasma membrane where it can interact with VP40 and GP to form the infectious virion. VP40 dimers are transported in an actin dependent manner, likely, with the aid of GTPase Rab14 and the host COPII vesicular transport system²²⁹⁻²³¹ to lipid rafts at the plasma membrane where they oligomerizes to forms linear hexamers and octamer rings²³². Lipid raft composition is important for the VP40 plasma membrane interactions, especially phosphatidylserine concentration^{233,234}. VP35, and VP24 are the essential proteins for the transport of the nucleocapsid to the plasma membrane while VP40 is dispensable for this process. Several studies have found that active transport of the nucleocapsid complex is dependent on the actin cytoskeleton and the nucleation

factor ARP2/3. The RAC1/WAVE1/ARP2/3 pathway was recently identified as important for the propulsion of the particles via actin comet tails²²⁷. It appears that the polymerization of F-actin propels the nucleocapsid forward towards the plasma membrane where it interacts with VP40 to drive the egress of the viral particle.

VP40, the most abundantly expressed EBOV proteins, is critical for particle and VLP production. Assembly and transport of the nucleocapsid can occur in the absence of VP40, however budding and incorporation of GP into the nascent virion cannot. Budding occurs at filopodia in an actin dependent manner likely driven by the interaction of the nucleocapsid with VP40^{225,227,235,236}. Similar to HIV Gag, EBOV VP40 contains late domains (L-domains) in the N-terminus which facilitate viral egress²³⁷⁻²³⁹. The EBOV L-domain is unique in that it contains two overlapping late domains, PTAP and PPxY, the deletion of which is sufficient to impaired budding^{160,239,240}. Like HIV, the ESCRT complex facilitates the budding of the virion from the plasma membrane and mediates the scission and release. Unlike HIV, the EBOV virion does not need to mature and is infectious as soon as it is released from the cell.

The immune system possesses many tools to combat these viruses. Among which is the small HERC family of proteins.

Figure 1.2. EBOV genome and replication cycle

A) The EBOV genome encodes for *GP* the glycoprotein GP_{1,2} as well as the secreted glycoproteins, *NP* the nucleocapsid protein, *VP35* the polymerase cofactor, *VP30* the transcriptional activator, *VP24* the RNA complex-associated protein, and *L* the large protein RNA-directed RNA polymerase. **B)** 1) EBOV replication cycle begins with attachment to the host cell membrane. Attachment can be mediated by several host surface proteins including C-type lectin, DC-SIGN and L-SIGN, and integrins such

as $\alpha 5\beta 1$ integrin, as well as TIM-1, TIM-4, and the TAM kinases TYRO3, AXL, and MERTK. 2) Macropinocytosis of the virion occurs through pathways similar to those used for apoptotic cells. Remodeling of the actin cytoskeleton is essential for this step. 3) The vesicle proceeds to mature into an early endosome and then into Rab7-positive late endosome/ lysosome compartments. The increase in acidity activates the cathepsin molecules. The GP1 subunit gets proteolytically processed in the late endosome by cysteine proteases Cathepsins B and L removing the mucin like domain and the glycan cap. 4) Binding of GP to the NPC1 receptor trigger conformational changes which are poorly understood to create a fusion pore and facilitating the release of the nucleocapsid into the cytoplasm where the replication of the genome can occur. 5) Transcription occurs within the ribonucleoprotein complex which contains NP, VP30, VP30, and L utilising the original viral genome and proteins. The mRNAs are sequentially transcribed from the 3' end to the 5' end with conventional start and stop codons preceding and trailing each gene. 6) Following transcription, all the nascent mRNAs, except for GP, are translated by the free ribosomal machinery in the cytoplasm. 7) When a certain level of NP protein is reached, it localizes near the ER forming the inclusion bodies which are a hallmark of EBOV infection. They appear in cells about 10 hours post infection, contain NP, VP35, VP30, VP24, VP40 and L. 8) Once the inclusion bodies are formed, they become the site of secondary translation. 9) GP is exported through the classical exocytic pathway with sGP being secreted into the extracellular milieu and GP_{1,2} remaining anchored to the plasma membrane awaiting virion assembly. 10) Access to a bipartite motif within the 3' leader region instructs the viral polymerase to synthesize a full-length antisense genome (red). The antisense genome (antigenome) serves as a template from which the future genomes are synthesized. 11) When the switch from translation to genomic replication occurs and viral RNA is available NP molecules bind to it displacing the VP35-NP interaction and allowing for the multimerization of NP around the nascent viral RNA. Encapsidation by multimerization of NP and VP35 of the viral RNA is cooperative with the extension of the genome and signifies the first step of particle formation. 12) The nucleocapsid is transported to the plasma membrane in an actin

dependent manner where it interacts with VP40 and GP to form the viral particle. 13) Virion budding occurs at filopodia in an actin dependent manner, this is likely driven by the interaction of the nucleocapsid with VP40. The ESCRT complex facilitates the budding of the virion from the plasma membrane and mediates the scission and release.

1.3 Small HERC Family of Proteins

Humans possess six HERC proteins and were originally classified as belonging to one HERC family based on their possession of one Regulator of Chromosome Condensation 1-like domain (RLD) and at least one homologous to E6AP C-terminus (HECT) domain. However, evolutionary analysis of animal HECT ubiquitin ligases by Marin in 2010 revealed that they are evolutionarily distant and belong to two subfamilies referred to as the “small” HERCs and the “large” HERCs²⁴¹. Additionally, his analysis proposed that the structural similarity, i.e., the presence of both an RLD and a HECT domain is due to convergence and that the RLD domains of the large HERCs and the small HERCs were attained independently. Evolutionarily, *herc4* appears to be the most ancient of the family from which *herc3* emerged through a gene duplication and chromosomal rearrangement event. This was followed by duplication of *herc3* into *herc6* and a duplication of *herc6* into *herc5*^{242,243}.

All the small HERC proteins (HERC3-6) contain a single RCC1 like domain at the N-terminus and a single HECT domain at the C-terminus linked by a spacer region (Figure 1.3 A). The spacer region is structurally disorganized and as of now has no known function. Although a recent study found that the RLD and HECT domains of HERC3 were dispensable for its binding to the NF- κ B subunit RelA suggesting that the spacer region may be involved in this interaction²⁴⁴. Additionally, in mice, the spacer region of HERC6 is essential for facilitating ISGylation. There, the HECT domain alone was not able to ISGylate proteins but when the spacer and the HECT domain were left intact ISGylation was able to take place²⁴⁵.

The RLD is found in the N-terminus and theoretically has the capacity to act as a guanine nucleotide exchange factor for Ran GTPases, however, its activity has thus far only been detected in HERC5^{246,247}. Early studies suggested that the RLD and spacer region is involved in the recognition of protein targets for ISGylation, however global ISGylation is not affected by the removal of the RLD domain in HERC5²⁴⁸⁻²⁵¹.

The HECT domain comprises the C-terminal portion of the small HERCs. It has been shown to possess E3 ligase activity in all the small HERCs and can conjugate ubiquitin (Ub) or ubiquitin-like molecules (Ubl) onto substrates. Unlike other E3 ligases the HERC proteins possess the ability to both bind and transfer Ub/Ubl molecules onto substrates²⁵². This process involves a cascade of reactions beginning with the ATP-dependent activation of the Ub/Ubl molecule by adenylation and the formation of a thioester bond with the Ub/Ubl at the active site cysteine²⁵²⁻²⁵⁴. The Ub/Ubl molecule transferred to the active site cysteine of the E2 conjugating enzyme which then transfers the Ub/Ubl molecule to the E3 ligating enzyme. The HECT domain of these proteins contains a cysteine residue (Figure 1.3 A, blue line in HECT domain) which forms a thioester bond with the Ub/Ubl and transfers it onto the substrate. The HECT domains of the small HERC proteins have catalytic activity similar to the E6-AP protein, for which they, are named and do not simply act as docking proteins for the E2 enzymes^{252,255,256}.

The small HERCs are differentially expressed in different tissues of the body and at varying levels throughout development. There are somewhat conflicting reports about the colocalization of the small HERCs with both the early endosomal compartments (colocalization with Rab5) as well as late endosomal and lysosomal compartments (colocalization with LBPA and CD68)^{242,247}. The discrepancies between these reports could be due to the use of different cell lines, different antibodies, different expression methods (endogenously expressed HERC proteins or transiently over-expressed tagged proteins), or lack of imaging resolution. Interestingly, HERC3 and HERC4 were found to coprecipitate with HERC6 in an over-expression assay; however, the functional relevance of this interaction is unknown²⁴².

Evidence from mRNA expression levels suggests that the function of HERC proteins varies based on their intracellular location (cytoplasmic versus nuclear), the presence of other co-expressed proteins (such as UBE1L, UbcH8, ISG15 and USP18 during IFN stimulation), or the tissue they are expressed in (testis versus epithelial cells). For example, in humans, the majority of ISGylation is performed by the E3 ligase HERC5 whereas in mice this function is performed by HERC6. Based on their temporal and special expression as well as tight regulation of their levels the HERC family of proteins play a key role in development and regulation of various cellular processes. Knowledge about the functions of the small HERCs as well as findings involving the functional consequence of ISGylation will be discussed in the following sections.

Domain	 RLD (RCC1-like domain)	 HECT (Homologous to E6AP COOH terminus)
Structure	Seven-bladed β -propeller	Bilobed

B

Image from the RCSB PDB (RCSB.org) (RCSB Protein Data Bank (RCSB.org): delivery of experimentally-determined PDB structures alongside one million computed structure models of proteins from artificial intelligence/machine learning (2023) *Nucleic Acids Research* 51: D488–D508 doi: 10.1093/nar/gkac1077). **C)** Cartoon depiction of the ISGylation pathway.

ISG15 is activated in an ATP dependent manner and attached to the E1 activating enzyme UBE1L. It is then transferred to the active site of the E2 conjugating enzyme UbcH8 which then transfers ISG15 to the E3 ligase HERC5 for attachment to the substrate. Image modified from Mathieu NA, Paparisto E, Barr SD, Spratt DE. HERC5 and the ISGylation Pathway: Critical Modulators of the Antiviral Immune Response. *Viruses*. 2021 Jun 9;13(6):1102. doi: 10.3390/v13061102.

1.3.1 HERC3

The *herc3* gene was first identified in a screen of previously unidentified genes larger than 2 Kb²⁵⁷. It is located on chromosome 4q22 and encodes a 117 kDa protein which produces different transcripts based on three different poly(A) sites^{243,247,258,259}. HERC3 is ubiquitously expressed and found at low levels in all cell types with significantly higher mRNA levels found in the fetal and adult brain, more specifically neuronal cells^{243,260}. Localization studies revealed a cytosolic distribution with a small amount found in membrane fractions. Further fluorescence microscopy studies showed that HERC3 colocalizes with the endosomal markers Rab5, ARF, RhoB and EEA1, and the

late endosomal and lysosomal markers LBPA and CD63^{242,247}. Colocalization with the Golgi network, endoplasmic reticulum, mitochondria, or peroxisomes was not observed²⁴². By virtue of its HECT domain, HERC3 is a ubiquitin binding E3 ligase and is itself a target of ubiquitination and proteasomal degradation, suggesting a self-regulatory mechanism²⁴⁷.

More recently, it was shown that treating T98G cells with the nuclear export inhibitor Leptomycin B resulted in pronounced nuclear localization of HERC3²⁶¹, however, previous studies did not demonstrate such an effect on Bovine aortic endothelial cells²⁴⁴, suggesting that HERC3 transits the nucleus in a cell type-specific manner.

Further studies have identified HERC3 as a regulator of cell senescence and proliferation as well as a mediator of autophagy through its confirmed interacting partners hPLIC-1 (also known as Ubiquilin1 (UBQLN1)) and hPLIC-2, the RelA component of NF- κ B, SMAD7, and MM1 protein^{242-244,261-263}. The ubiquitinated version of HERC3 was also shown to interact with human proteins linking integrin-associated proteins and the cytoskeleton (hPLIC-1 and hPLIC-2). Ubiquitination of HERC3 did not result in its degradation but instead was shown to stabilize the protein. It is thought that binding of hPLIC-2 to ubiquitinated HERC3 inhibits its interaction with the proteasome and subsequent degradation²⁴².

The active site cysteine at position 1018 of HERC3 contributes to higher levels of overall²⁴⁴ ubiquitination but does not appear to be essential for this function. For example, the active site cysteine is not necessary for HERC3 mediated regulation of NF- κ B. HERC3 inhibits the nuclear translocation of NF- κ B subunit RelA through its ubiquitination at lysine 195 and 315 after disassociation from the I κ B α subunit. Together with ubiquilin 1 (UBQLN1), HERC3 targets the ubiquitinated protein to the 26S proteasome. Interaction with UBQLN1 was important for this regulation but the catalytic HECT domain was not necessary²⁴⁴. Interestingly, the active site cysteine is indispensable for the ubiquitination of the Myc modulator 1 protein (MM1) by HERC3²⁶³. This is part of a regulatory loop of cell senescence whereby Δ Np63 α , an isoform of the p63 transcription factor, induces

transcription of HERC3 leading to the ubiquitination and degradation of the MM1 protein by the proteasome. A decrease in cellular MM1 protein leads to aberrant expression of c-Myc and its downstream target cyclin dependent kinase (CDK) 4, an important subunit in the protein complex responsible for the progressing of the cell cycle from G1 to S phase. This results in a loss of cell senescence and an increase in cell proliferation. Accordingly, HERC3, c-Myc and p53 expression is higher in invasive breast carcinoma²⁶³.

Dysregulation of this axis is also evident in UVB-induced photoaging. Exposure to UVB radiation resulted in repression of $\Delta Np63\alpha$ and a decrease in *herc3* transcription leading to more MM1 in the cells and subsequent proliferative senescence of keratinocytes²⁶⁴. Its involvement in cancer regulation has also been implicated by single nucleotide polymorphism studies whereby SNPs in the *herc3* gene are related to the metastatic phenotype of the tumor²⁶⁵. Along the same lines, HERC3 has been implicated in the promotion of epithelial to mesenchymal cells transformation (EMT) in glioblastomas²⁶¹. A common chemotherapy for glioblastoma multiforme (GBM) is Temozolomide which, unfortunately, induces autophagy and EMT²⁶⁶. In a recent study, Hong Li, and colleagues²⁶¹ found that HERC3 is involved in this process. Temozolomide induces HERC3 expression leading to the ubiquitination/autosomal degradation of SMAD7 and activation of TGF β signaling pathway. This group also showed that GMB subtypes with low HERC3 expression survived longer and that the chemoresistance of GMB was related to HERC3 levels²⁶¹.

In summary, HERC3 was identified as ubiquitin binding E3 ligase and further studies have defined it as a regulator of cell senescence and proliferation as well as a mediator of autophagy in glioblastoma cells. Different methods of investigation and different technologies have provided glimpses into the localization, function, and importance of HERC3. Continuing the research into this important molecule will provide a clearer picture into functional importance in the whole organism.

1.3.2 HERC4

The HERC4 protein was first discovered during a screen for HERC3 and HERC5 proteins in different tissue types. It is comprised of 1057 amino acids encoded by the *herc4* gene on chromosome 10q22²⁴³. Its localization is predominantly cytoplasmic, although, an altered nuclear localization is reported when transcription factor c-Maf is over-expressed²⁴³. In terms of tissue, HERC4 is highly expressed in the fetal brain with moderate expression in the adult brain and testis²⁴³.

The most widely studied function of HERC4 is its involvement in various cancers where both pro- and anti-cancer properties have been reported. In solid tumors, upregulation of HERC4 was found to lead to metastasis and invasion of the cancer. Studies using breast cancer cell lines as well as intraductal carcinoma and invasive ductal carcinoma biopsies found that HERC4 was significantly unregulated in these tissues compared to adjacent normal breast tissue at both the mRNA and protein levels²⁶⁷⁻²⁶⁹. The increased expression of HERC4 correlated with the clinical stage and histological grade of invasive ductal carcinoma suggesting that over-expression of HERC4 leads to metastasis of cancer cells^{268,270}. In the breast cancer cell lines MCF-7 and MDA-MB-231, HERC4 was upregulated compared to the normal breast cell line MCF-10A and its knockdown reduced cell survival, proliferation, and migration. HERC4 expression in breast cancer cell lines is regulated by miRNA-1285-3p and miRNA-136-5p whereby expression of these miRNAs leads to reduced levels. The mechanism by which HERC4 over-expression induces metastatic properties in these cells appears to involve HERC4-mediated ubiquitination and degradation of the tumor suppressor gene LATS1, which is a component of the Hippo signaling pathway²⁶⁷. Similar results were observed in hepatocellular carcinoma and lung cancer cell line A594, where increased expression of HERC4 led to an increase in cell proliferation and migration^{271-273,267}. Reduction of HERC4 expression in HPV-infected cervical cancer cell lines via the chemical compound Andrographolide led to an increase in expression of the anti-tumor protein p53 and an increase in cell death²⁷⁴.

On the other hand, there are several studies which attribute an anti-cancer effect to HERC4 expression. In non-small cell lung cancer (NSCLC) HERC4 protein levels were found to be reduced compared to normal lung tissue²⁷⁵. Downregulation and not over-expression of HERC4 lead to cell proliferation in these studies. This was correlated with HERC4 mediated ubiquitylation and degradation of Smoothened (Smo), a highly conserved protein in the hedgehog signaling pathway which plays a crucial role in embryonic development²⁷⁵. A similar trend was observed in liquid tumors such as multiple myeloma (MM), where HERC4 downregulation was correlated with cell proliferation and cancer progression²⁷⁶. In these experiments, HERC4 was identified as the E3 ligase responsible for the ubiquitination and subsequent degradation of c-Maf, a transcription factor which regulates the expression of several key drivers of cell cycle progression. Interestingly, during c-Maf over-expression HERC4 localization was altered from being cytoplasmic to being nuclear²⁷⁶. Altogether, these findings suggest that downregulation of nuclear HERC4 can lead to the formation of cancers while upregulation of HERC4 in certain cell types can lead to the development of metastasis.

Due to its high expression in the testes, some of the first functional experiments investigated the effect of HERC4 on fertility. In male mice, HERC4 deficiency caused a 50 percent reduction in fertility, while their female counterparts did not demonstrate any deficiencies in fertility, physiology, or behavior²⁷⁷. The fertility defect was linked to a reduction in sperm motility due to an abnormality in the flagellum. HERC4 deficient mice had a higher percentage of sperm with angulated tails due to the retention of a cytoplasmic droplet²⁷⁷. Similarly, dysregulation of HERC4 via administration of *Tripterygium wilfordii*, a plant used in Chinese medicine, or the parasite *Neospora caninum* also resulted in a decrease in fertility in mice^{278,279}.

HERC4 is an evolutionarily ancient protein believed to have emerged approximately 595 million years ago. In *Drosophila* it has been implicated in tissue growth and remodeling pathways involving Hippo protein kinases. The HERC4 orthologue was found to target the scaffolding protein Sav to degradation to maintain tight control over its levels²⁸⁰.

However, in *Drosophila* there is only one large HERC family member (HERC2) and one small HERC family member (HERC4) so whether this effect is translatable to mammals or humans remains to be investigated. *Drosophila* studies with HERC4 also found that HERC4 ubiquitylates and targets for degradation the Hedgehog pathway protein Smoothed (Smo), which is a G protein-coupled receptor involved in embryogenesis and tissue homeostasis^{275,281}.

In fish, HERC4 was found to have several antiviral functions. In Senegalese sole, HERC4 levels were significantly higher when fish were infected with a wildtype strain of nervous necrosis virus (NNV) compared to a less lethal mutant strain, a trend also observed for HERC5 and ISG15²⁸². The higher expression of HERC4 and other innate immune response elements is believed to be due to the higher viral load observed in the tissues post infection despite the same inoculation provided with both the wildtype and mutant virus. Vaccination of Senegalese sole with a recombinant NNV resulted in upregulation of HERC4 both in response to the vaccine and in response to a viral challenge 30 days post-vaccination²⁸³. While in Atlantic cod HERC4 expression was slightly lower in the brain of symptomatic fish infected with the Nodavirus Atlantic cod nervous necrosis virus (ACNNV) compared to the asymptomatic Atlantic cod²⁸⁴. HERC4 was also identified as one of the most highly upregulated genes in Atlantic cod macrophages challenged with a dsRNA homologue iPC²⁸⁵. This coincided with a high expression of ISG15. These findings support the theory that HERC4 is highly induced by viral infection and as such, acts as the main E3 ligase for ISG15 in Atlantic cod. Replacement of HERC5 as the main E3 ligase has been observed in mice and pigs where HERC6 functions as the main cellular E3 ligase for ISG15²⁸⁶⁻²⁸⁸. In human cell lines, HERC4 is not strongly induced by interferon β , but its homologues HERC5 and HERC6 are interferon-induced and act as key mediators of the Type I interferon response.

1.3.3 HERC5

Originally designated as CEB1 (Cyclin E binding protein 1), HERC5 was identified in a yeast two-hybrid screen of cyclin-E and p21 binding partners²⁸⁹. The functional results

of this interaction were not investigated but HERC5 expression was increased in cells where the tumor suppressor proteins RB and p53 were absent or non-functional. HERC5 mRNA expression was shown to be induced by interferon, LPS, TNF α , and IL1- β in endothelial cells, suggesting that HERC5 plays an important role in innate immunity²⁹⁰. HERC5 proteins and mRNA are moderately expressed in the heart and placenta, and very highly expressed in the testis, spermatogonia and spermatocytes³¹⁴. Among immune cells, its highest expression is within regulatory T-cells and neutrophils. However, it is not considered to be highly expressed under normal conditions but induced by infection and interferon stimulation. HERC5 protein expression does not always correlate with *herc5* mRNA levels since HERC5 protein levels were shown to remain low despite significantly increased mRNA levels, suggesting that HERC5 protein expression is tightly regulated²⁹⁰.

One of the main functions of HERC5 is its contribution to the conjugation of the ubiquitin-like protein ISG15 to target substrates. HERC5 is the main E3 ligase for ISG15 although TRIM25 and HAARI have also been known to attach ISG15 to specific target substrates²⁹¹⁻²⁹³. Type I interferon treatment induces the expression of ISG15 and all three members of the ISGylation system: the E1 activating enzyme UBE1L, the E2 conjugating enzyme UbcH8, and the E3 ligase HERC5. Interestingly, all three proteins were found to be substrates for ISGylation, suggesting a negative feedback loop could be regulating their expression. There is crosstalk between the ISGylation and the ubiquitination systems at the E2 level whereby both the E1 for ubiquitin and the E1 for ISG15 can bind to and transfer the Ubl molecule to it through a thioester bond. HERC5 in turn can also accept both ISG15 from UbcH8 and Ub from UbcH5²⁹¹⁻²⁹³. Most of the biochemical studies of HERC5 have involved the conjugation of ISG15 to substrate molecules. These will be discussed in the ISG15 and ISGylation section which follows.

Two ISGylation independent functions of HERC5 have been identified thus far, both involving the RLD domain. First, the RLD domain of HERC5 was found to coprecipitate with Ran and effect the export of REV dependent (unspliced) HIV RNA from the nucleus

to the cytoplasm by reducing intracellular levels of RanGTP and/or inhibiting the association of RanGTP with RanBP1²⁴⁶. With the ability of HERC5 to interact with Ran, it is possible that HERC5 binds and sequesters Ran in the cytoplasm, interfering with RanGDP shuttling into the nucleus. Another possibility is that HERC5 stimulates guanine nucleotide release from Ran in the cytoplasm similar to HERC1 which stimulates GDP release from the small GTPase proteins ARF1, ARF6 and Rab^{246,294,295}. Other than the disruption of nuclear export of Rev dependent HIV-1 RNA, little is known about the functional effects this relationship has on the cell. The second ISGylation independent function of HERC5 is the ability to reduce intracellular viral RNA of Ebola VP40 in a manner specific to the RLD domain. This is discussed in detail in Chapter 4 of the thesis.

Due to its interferon induced nature, some of the most obvious functions of HERC5 are in pathogen eradication. To that end, several high throughput genomic studies have found a significant relationship between HERC5 expression and pathogenic infections. For example, Chikungunya virus infection increases the amount of HERC5 in cells 250-fold²⁹⁶ while malaria infection byproducts significantly increased expression in PBMCsⁿ²⁹⁷. At 24 hours post ingestion the expression of HERC5 mRNA returned to baseline levels which is consistent with previous findings suggesting that HERC5 expression is tightly regulated and is highest at 21 hours post infection then drops off²⁹³. Another study found that HERC5, ISG15 and HERC6 expression is related to the severity of Hand Foot and Mouth disease virus. DNA methylation of the region preceding the gene *DDX58*, encoding the dsDNA sensor RIG-1, reduced activation of IRF3 by HFMD EV1 and the expression of HERC5, HERC6 and ISG15, resulting in more severe disease²⁹⁸.

The technological advancements of RNA sequencing have brought on additional information about HERC5 expression in healthy and diseased states. HERC5 expression has been linked to various cancers, however, HERC5 expression, classification (tumor suppressor or oncoprotein), and binding partners identified differ based on the type of cancer in question. Copy number loss of the chromosome 4q region which contains HERC5 and reduced HERC5 expression has been linked to poor prognosis or advanced

disease stages in pancreatic cancer, colorectal cancer, and non-small cell lung cancer (NSCLC).²⁹⁹⁻³⁰¹. HERC5 expression was found to be lower in colorectal cancer³⁰⁰ and HCC³⁰⁰ samples compared to normal adjacent tissues. It contributes to the ubiquitination and likely degradation of transcriptional coreceptor C-terminal protein 1 (CtBP1) which regulates the suppression of multiple proapoptotic genes³⁰⁰. In the colorectal cancer model overexpression of HERC5 or inhibition of CtBP1 resulted in increased sensitivity to chemotherapeutic drugs³⁰⁰. These results are similar to the role HERC5 plays in non-small cell lung cancer, where hypermethylation of HERC5 promoter (located at 4q22.1), and thus under-expression of the gene correlated with positive disseminated tumor cells in the bone marrow, brain metastasis, and poor survival in both stage I adenocarcinoma and metastatic lung cancer patients. Normal lung tissue does not have HERC5 methylation but HERC5 methylation was found to be common in brain cancer samples resulting from this metastasis^{302,303}.

Conversely, HERC5 overexpression increased cell survival in the hepatocellular carcinoma cell lines HepG2 and SMMC-7721 and HERC5 knockdown increased apoptosis, p53 and BAX levels³⁰⁴. A chemical compound HZ-6d which downregulates HERC5 and ISG15 expression led to the activation of the p53 pathway³⁰⁴. In breast cancer studies HERC5 expression is associated with tumor grade, tumor stage and lymph node metastasis³⁰⁵. Here, qRT-PCR results showed that HERC5 was significantly higher in cancer tissues compared to adjacent healthy tissues and knocking down HERC5 inhibited tumor cell proliferation. Interestingly, USP18 was inversely associated with prognosis and its overexpression inhibited tumor cell proliferation, suggesting that the effect HERC5 has on cell proliferation is linked to its role as an ISG15 E3 ligase³⁰⁵. Similarly, in epithelial ovarian cancer chemotherapy resistant cell lines express 8 times more HERC5 than chemotherapy sensitive cell lines. The researchers believe this is related to HERC5 ISGylation of and degradation of p53 leading to aberrant cell proliferation³⁰⁶. Furthermore, recurrent tumor tissue has increased levels of CCL20 resulting from decreased expression of HERC5. CCL20 is the only chemokine overexpressed in tumor tissue where it can recruit Tregs, creating an immunosuppressive

tumor microenvironment which leads to poor prognosis³⁰⁷. Taken together these conflicting results provide a blurry picture about the role of HERC5 in cancer tissues.

In terms of other disease, HERC5 has been identified as a significant differentially expressed gene or influential factor in gestational diabetes mellitus (GDM)³⁰⁸. HERC5 mRNA expression is higher in pregnant women experiencing gestational diabetes and through the RLD domain, HERC5 is predicted to interact with the long noncoding RNA GAS5 and the neuropeptide precursor TAC1, both which are known influential factor in GDM³⁰⁸. lncGAS5 is reduced in the peripheral blood and renal tissue of patients suffering from GDM, diabetes mellitus, and neuropathy, likely through a mechanism involving HERC5, similar to the mechanism employed to reduces EBOV viral RNA (Chapter 4)³⁰⁹. The details of this interaction are theoretical (through predictive interaction models) and further studies are needed to elucidate the mechanism and specificity by which HERC5 can reduce intracellular levels of RNA. Along the same lines HERC5 was identified as a hub gene in protein interaction network for Lupus nephritis (LN)³¹⁰⁻³¹². HERC5 expression was increased in samples LN compared to matching controls. Together, this evidence supports a pathological role for aberrant over-expression of HERC5 in the kidneys, where under normal conditions HERC5 has very low protein and RNA expression^{313,314}.

These studies provide evidence that under normal conditions (immune activation is not occurring), HERC5 regulation is essential to maintain natural function of the cell. Dysregulation of HERC5 expression can lead to a disease state whether it be cancer or autoimmune disorders.

1.3.4 HERC6

Herc6 was first identified in a screen for *herc3* and *herc5* genes in various tissues²⁴³. Although the initial discovery of HERC6 reported low expression among the cell types tested (< 5-fold), it was later shown that HERC6 is induced by changes in the cellular environment. Like HERC5, HERC6 is interferon-induced and in many animals it is

considered a potent antiviral molecule^{286,295,315}. A recent evolutionary study which examined HERC5 and HERC6 proteins over mammalian evolution found evidence that there was a HERC5 duplication and reorganization with HERC6 which formed a chimera containing the HERC5 RLD and spacer regions but the HERC6 HECT domain³¹⁶. The signature of deletions, insertions and multiple amino acid replacements suggests that HERC6 has undergone pathogen driven positive selection. Further, the spacer region of HERC6 was identified as the likely pathogen interaction interface due to the number of positive selection sites it contained across different species, a finding which is in contradiction to the current belief that its E3 activity is the main function of HERC6³¹⁶.

The majority of the HERC6 research has focused on mice where HERC6 is the main E3 ligase for ISG15, in similar fashion which HERC5 mediated ISGylation occurs in humans²⁸⁶. Recent reports suggest that HERC6, not HERC5, is the main E3 ligase in pigs and the human ISGylation machinery is not able to conjugate porcine ISG15⁴⁰⁴. This was identified through a mass spectrometry screen of porcine ISGylated proteins and further biochemical analysis is required to confirm these findings. Similar to the other small HERCs, HERC6 is localized predominantly in the cytoplasm. Interestingly, HERC6 was found to interact with both HERC3 and HERC4 in a manner independent of its active site cysteine, suggesting that the small HERCs might form heterodimers or influence each other activity through direct interactions²⁴².

To study the functions HERC6 might perform independent of its role as the main E3 ligase for ISG15 a system of knockout mouse model was developed. As expected, knockout mice which lack HERC6 also lack ISGylation, cementing its role as the main E3 ligase for ISG15^{286,317}. However, knockout mice for UBE1L, the E1 protein required for the activation of ISG15 also lack ISGylation, thus, physiological characteristics which are shared between the two mice can be considered ISGylation specific and physiological characteristics only found in HERC6 knockout mice can be attributed to HERC6 alone³¹⁷. One such effect is seen in sperm sack morphology of knockout mice³¹⁷. These mice display epithelial hyperplasia in the seminal vesicles, a defect not observed in UBE1L

knockout mice despite their lack of ISGylation. The exact role of HERC6 in male fertility has yet to be deciphered but a study of DNA methylation profiles in human sperm of smokers and non-smokers found that HERC6 DNA methylation is reduced in smokers. Smokers in this study also had reduced semen volume, reduced sperm count, and reduced spermatozoa motility³¹⁸.

The recent era of computational biology and genomics has highlighted the expression profile of HERC6 in different situations, mainly organismic stress induced by viral infections and cancer. In terms of its antiviral activities, it has been studied in relation to Influenza B virus, vesicular stomatitis virus (VSV), Newcastle disease virus (NDV), respiratory syncytial virus, human rhinovirus infections, Hepatitis C, West Nile virus, and HIV as well as in relation to parasitic resistance and *Mycobacterium avium* resistance; however, this has mainly been linked to its ability to act as the main E3 ligase for ISG15 in mice^{319–322}.

Interestingly, studies looking for gene signatures to distinguish between the different immune responses elicited by viruses and bacteria found that HERC6 expression is part of an 11 gene signature which was able to distinguish between bacterial and viral respiratory infections in a clinical setting³²³. This gene signature which contained 10 other interferon induced genes, including HERC5, could also distinguish influenza virus infection from other viral infections such as respiratory syncytial virus and human rhinovirus infections. Expression of these genes also increased in participants who produced an immune response in reaction to the influenza virus vaccine and can potentially be used to determine if vaccination was successful³²³. This was corroborated in a more recent study examining the gene signatures predictive of SARS-CoV-2 or bacterial respiratory infection. Here, a three gene signature of HERC6, IGF1R and NAGK had a sensitivity of 97.3% (85.8–99.9), and specificity of 100% (63.1–100) when distinguishing between viral and bacterial infection and sensitivity of 88.6%, and specificity of 94.1% when identifying COVID-19 infections, a significant improvement

to the current measurements of C-reactive protein and leukocyte counts currently used for these predictions³²⁴.

HERC6 was also implicated as an important early expression gene in the battle against Hepatitis C. The least expensive treatment for Hepatitis C is a 48-week course of pegIFN/ribavirin, which has a high probability of failure and causes severe side effects to the patient³²⁵. Lu et al. (2016) found that the early expression of 8 genes including HERC5 and HERC6 were able to accurately predict which patients would respond well (sustain a virological response) and which would benefit from a different course of treatment. Compared to those with non-sustained virological response patients with sustained virological response had increased expression of HERC5, HERC6, ISG15 and USP18 at week one post treatment³²⁵.

Surprisingly, HERC6 has also been implicated as an important gene for agricultural breeders. RNAseq studies have linked HERC6 expression to body weight determinants in sheep and cows. In sheep it was identified as an important gene influencing economic traits such as muscle weight in carcass, body weight, and milk protein percentage^{327,328}. HERC3, HERC5, and HERC6 SNPs are associated with resistance to parasites and as such were identified as targets for breeding of sheep to develop antiparasitic resistance³²⁹. Whereas in cows, HERC6 was identified as a protein important to the transference of feed intake into body fat and protein³³⁰. Additionally, Cattle which developed severe disease and had to be treated multiple times for respiratory disease had increased expression of type-I interferon activity (HERC6, IFI6, ISG15, MX1).

Overall, these studies suggest that the regulated expression of HERC6 is linked to a healthy immune system which is able to efficiently fight off pathogens and maintain normal metabolic function.

1.3.5 ISG15 and ISGylation

Initially identified as just another interferon induced gene, ISG15 was later classified as a ubiquitin like molecule (Ubl) with potent antiviral properties³³¹. ISGylation involves the

covalent posttranslational attachment of ISG15 to host and viral target substrates by a specialized group of IFN- α/β induced E1-E2-E3 ubiquitin cascade enzymes. For example, protein-protein interaction studies have shown that ISG15 only coordinates with five of the over 600 identified E1-E2-E3 enzymatic members³³². The ISGylation pathway begins when UBE1L activates ISG15 through an ATP-dependent mechanism to form a thioester bond between the C-terminal carboxyl of ISG15 and the catalytic cysteine of UBE1L^{333,334}. Following activation, ISG15 is transferred by UBE1L to UbcH8 via a trans-thiolation reaction that forms a thioester bond between the C-terminus of ISG15 and the conserved catalytic cysteine residue of UbcH8^{335,336}. The UbcH8-ISG15 thioester complex then transfers its ISG15 cargo to the catalytic cysteine (C994) of the ISG15-specific homologous to E6AP C-terminus (HECT) E3 ligase HERC5. Thereafter, HERC5 catalyzes the covalent attachment of ISG15 onto host and viral substrate proteins by forming an isopeptide bond between the C-terminus of ISG15 and the ϵ -amino group on the lysine of the respective protein target^{337,338}. See Figure 1.3 C.

The ubiquitylation pathway enzymes are constitutively expressed and can form a variety of ubiquitin chain linkages with their target substrates³⁴¹⁻³⁴⁴. On the other hand, the ISG15-specific E1-E2-E3 cascade enzymes are only induced following inflammation and exclusively form monomer isopeptide linkages³⁴⁵. This suggests that the ISG15 signaling pathway provides the cell with a highly specialized and tightly regulated antiviral function at the expense of dysregulating vast cellular activities³⁴⁶. While ubiquitination of proteins often leads to their degradation by the proteasome, most studies suggest that ISGylation does not lead to degradation of proteins but more often to the protection from ubiquitination and subsequent degradation. Accordingly, the most reported function of ISGylation is altered protein localization and modified protein function.^{245,249-251,288,355-359} Interestingly, a recent publication observed that hybrid ISG15-ubiquitin chains can also be formed by the cell to regulate protein homeostasis suggesting the interplay between ubiquitin and ISG15 is not completely understood³⁴⁷.

The expression of the ISGylation system has a significant impact on the cellular environment and normal protein function, making its stringent regulation essential for cell survival³⁴⁹. Hyper-ISGylation through the deletion of USP18, the main de-ISGylase, often leads to apoptosis in hemopoietic tissue, brain cell injury, and decreased life expectancy in mice²⁴⁹. Whereas in humans, ISG15 deficiencies are extremely rare but not fatal. These diseases are associated with mycobacterial hypersensitivity, brain calcification, and skin lesions^{353,354}. Therefore, understanding how ISG15 influences cellular function during a viral infection is essential to clarifying the diverse range of biochemical outcomes that can occur as a consequence of host ISGylation activity.

ISG15 falls in the “ISGF3/IRF-3” group of interferon stimulated genes, meaning that both IRF-3 and ISGF3 can induce its expression in cells³⁴⁸. Expression of UBE1L, UbcH8 and HERC5 occurs through the IRF-3 pathway following detection of viral pathogens as well as through the ISGF3 pathway following induction of Interferon α/β ^{349,350}. HERC5 expression can be induced by IL-1 β and TNF α although not to the extent that is observed with Interferon β , and more recent studies have suggested that the ISGylation system can be induced by NF- κ B^{351,352}.

A 2003 study conducted by Malakohova et al. was the first to identify that ISG15 positively regulates the host antiviral response³⁶⁰. This was a follow-up study to a high-throughput western blotting screen which identified PLC γ 1, ERK-1, JAK-1 and Stat1 as being ISGylated³⁶⁰. They found that in UBP43 (also known as a USP18) null cells there was a maintenance of strong interferon response and hypersensitivity to interferon inducers such as poly(I:C). Additionally, the JAK/STAT pathway activation was maintained for longer in USP18 null, ISGylation proficient cells. Reconstitution of protein ISGylation lead to increased interferon signaling in these studies. Meanwhile, in LPS induced inflammation of microglia cells, ISGylation of Stat1 increased its stability and the expression of downstream target proteins implicating it as a positive regulator of the antiviral response³⁶¹. Soon after, additional evidence emerged indicating that ISG15 and ISGylation contribute to the regulation of the innate immune response. For example,

ISGylation of Interferon regulatory factor 3 (IRF3) by HERC5 leads to its stabilization³⁶²⁻³⁶⁴. Following detection of viral PAMPs by TLR3 and TLR4 or detection of viral RNA by the cGAS/STING pathway IRF3 is phosphorylated, dimerizes, and is translocated into the nucleus where it acts as a transcription factor for Type1 interferons and proinflammatory genes³⁶⁵. The potency of this protein requires a finely tuned response to environmental signals and is evident by the multitude of post-translational modifications which control activation and function. HERC5 ISGylates IRF3 at lysines 193, 360, and 366, inhibiting its ubiquitination by Pin-1 and subsequent degradation. Stabilization of IRF3 by ISGylation acts as a positive feedback loop to sustain the induction of interferons, interferon stimulated genes, and prevent the premature termination of the antiviral response³⁶⁴.

Additionally, early studies found that UbcH8 and ISG15 conjugation are involved in the regulation of RIG-I by inhibiting its activation via ubiquitination^{335,366}. RIG-I and melanoma differentiation-associated protein 5 (MDA5) are major RNA sensors in the cytosol and together represent the RIG-I-like receptors (RLR) family of antiviral proteins. Binding of foreign or mislocated RNA to the C-terminal domain and helicase of RIG-I and MDA5 switches these molecules into the active state, initiating an enzymatic cascade ending with the activation of an antiviral state. ISG15 participates in a negative feedback loop whereby ISGylated RIG-I is not able to be ubiquitinated by TRIM25 and activated for downstream signaling but instead can be ubiquitinated by RNF125 and targeted for degradation³⁶⁷. RNF125 increases RIG-I, MDA5 and IPS-1 ubiquitination and destabilization leading to decreased IFN β stimulation³⁵⁷. The recent COVID-19 pandemic stimulated research into the sensing of RNA viruses leading to the discovery that MDA5 ISGylation is important for the induction of an antiviral response³⁵⁷. MDA5 is a major RNA sensor in the cytosol and ISGylation at position K32 and K43 following PP1 mediated CARD dephosphorylation lead to the stabilization and higher order oligomerization of MDA5³⁶⁸. This regulatory role for ISG15 on MDA5 is contrary to its role on the activation and stability of RIG-I raising the possibility that ISG15 acts as a sensor switching modification in this context. As the levels of ISG15 in the cell rise they

promote MDA5 stability, activation, and cytokine induction while concomitantly deactivating RIG-I³⁶⁸.

Furthermore, over-expression of the ISGylation system has been found to negatively regulate the activation of the NF- κ B pathway. Phosphorylation of TAK1 leads to the ubiquitination through ISGylation and inactivation of Ubc13, an important ubiquitin E3 enzyme in the pathway³⁵⁵. More recent studies found that ISGylation of mitochondrial proteins is important for the stability of the mitochondria as well as the antiviral response to Vaccinia virus in murine bone derived macrophages. Additionally, this group found that mitophagy and oxidative phosphorylation were impaired in ISG15 null cells³⁶⁹.

ISGylation and the ISGylation machinery have also been implicated in the regulation of autophagy³⁷⁰. ISGylation of BECN-1 following type I interferon induction was found to inhibit autophagy and restrain viral replication³⁷¹. In 2019, Zhang et al³⁷² identified additional ISGylation targets in *Listeria monocytogenes* infected mouse livers using quantitative label-free proteomics. They confirmed the ISGylation of 87 substrates previously known to be ISGylated and added an additional 347 proteins to that list. They found that in this model, ISGylation resulted in an increase in extracellular vesicle and protein secretion. Additionally, *Listeria* infection resulted in an increase of ISGylated mitochondrial proteins. In many cases the site of ISGylation overlapped with acylation sites, dimerization domains, and active sites further supporting ISGylation as a regulatory mechanism in the antimicrobial response.

The studies mentioned above demonstrate that ISGylation feeds into self-regulatory feedback loops which control the expression of a multitude of interferon stimulated genes, for which both positive and negative effects have been observed on upstream effectors of the antiviral response. In biologically relevant contexts, the most likely scenario is that the induction of the ISGylation system has a regulatory effect, the sum result of which is dependent on the quantity of viral proteins and RNAs that are sensed, the expression levels of ISGs, and the temporal progression of the host-virus battle. During the early stages of infection, ISGylation of key immune factors likely feeds into a

positive feedback loop increasing the production of antiviral proteins and inhibiting the premature termination of the interferon response. Later, as the immune response controls the infection, it likely feeds into negative feedback loops, preventing the maintenance of unnecessary inflammation and resulting tissue damage.

The antiviral effects of ISGylation have been identified against several viral proteins. For example, ISGylation (i) stalls IAV replication by blocking NS1 protein homodimerization³⁴⁶, (ii) promote HCV proliferation via improved cyclophilin A recruitment by NS5A proteins³⁷³ and, alternatively, (iii) inhibit an early stage of HIV assembly by attenuating Gag-particle production^{132,374}. In the upcoming sections I will present some of the recent discoveries involving the ISGylation of viral protein targets.

1.3.5.1 Role of ISGylation in HCV replication

The antiviral effects of HERC5 and ISG15 on HCV were first observed by Jung Kim et al., who were examining mechanisms of HCV replication cycle inhibition³⁷⁵. By conducting site-directed mutagenesis experiments on the HCV protein NS5A, the group was able to demonstrate that HERC5 inhibits HCV replication by ISGylating NS5A at lysine 379 (K379) which subsequently targets it for K48 polyubiquitylation by an unknown E3 ligase³⁷⁵. The researchers confirmed this antiviral activity by demonstrating that HCV replication was unrestrained when ISG15 and its corresponding E1–E2–E3 enzyme cascade were expressed in the presence of HCV NS5A K379R variant proteins. Taken together, these findings suggest that NS5A is the primary HCV target substrate of HERC5-dependent ISGylation, and that K379 is the sole NS5A residue that HERC5 targets for ISGylation. More recently, Abe et al. demonstrated that the HCV NS5A protein is prone to ISGylation at five Lys residues (K44, K68, K166, K215 and K308)³⁷³. In fact, one of the ISG15 attachment points on NS5A, K308, is located within the NS5A-binding region for cyclophilin A (CypA), a virulence factor that is required for efficient HCV cellular propagation. Thus, HERC5 ISGylation of NS5A at K308 enhances HCV recruitment of CypA to provide a pro-virulent replication activity, a direct contradiction of previous findings from Kim et al.³⁷⁵. Moreover, a stand-alone study conducted by

Domingues et al. found that ISG15-related forms of HCV inhibition occur independently of HERC5 activity³⁷⁶. To date, no follow up research has been conducted on the HERC5–HCV ISGylation system to confirm whether HERC5 ISGylation activity results in a pro- or anti-virulent response to HCV infection, and whether HERC5 is necessary for catalyzing the modes of ISG15 inhibition that have been observed for HCV NS5A proteins.

1.3.5.2 Role of ISGylation in Influenza Virus replication

New research by Tang et al. has shown that HERC5 targets IAV NS1 for ISGylation to prevent IAV capsid formation³⁴⁶. Using pulldown assays and immunoprecipitation analysis, the researchers found that HERC5 interacts with the ribosomal-binding (RBD) and C-terminal effector domains (ED) of NS1, and that both interactions were required to form stable HERC5–NS1 complexes³⁴⁶. Lysine residue substitutions in IAV NS1 also revealed that HERC5 attaches ISG15 at multiple NS1 lysine residues (K20, K41, K217, K219, K108, K110 and K126), with the strongest inhibitory effect coming from the ISGylation of the K126 and K217 residues in the ED and RBD domains, respectively³⁴⁶. The ISGylation of NS1 subsequently abolished the ability of NS1 to interact with protein kinase R (PKR) and blocked NS1 RBD-dependent homodimerization, thereby significantly inhibiting IAV capsid assembly *in vivo*³⁴⁶. Certain avian flu IAV strains, such as H5N1, demonstrated a higher rate of NS1 K217R mutation compared to most seasonal flu strains^{346,377}. It was also observed that avian IAV variants were less susceptible to ISGylation at K126, suggesting that, unlike other IAV strains, avian IAV NS1 proteins may adopt a new structure that obstructs the K126 ISGylation site from HERC5. Given that K126 and K217 have been determined as the primary ISGylation sites involved with preventing IAV capsid formation, these discoveries provide a possible explanation for why avian strains of the flu are more infectious and lethal than other IAV strains. Despite HERC5 demonstrating minimal antiviral activity against certain avian IAV strains, these findings from Tang et al. indicate that HERC5 and its ISGylation activity could serve as prime drug targets for the development of treatments that are used to combat most seasonal IAV strains.

1.3.5.3 Role of ISGylation in HIV and retrovirus replication

A pivotal study by Woods et al. in 2011 confirmed that HERC5 prevents an early stage of HIV-1 viral assembly by ISGylating proteins involved with Gag polyprotein (Pr55Gag) particle production¹³². The researchers used confocal immunofluorescence microscopy to reveal that IFN-I-induced HERC5 localizes to the cytoplasm where it forms punctuate bodies in a variety of cell lineages, and that these bodies interact with polyribosomes¹³². These findings were consistent with a previous study conducted by Durfee et al., who observed that HERC5 associates with the 60S ribosomal subunit of the polyribosome using cell fractionation^{248,255}. Additionally, IFN-I-induced HERC5 and HIV Gag proteins colocalize to the plasma membrane where HERC5 ISGylates Gag particles to prevent HIV-1 viral budding. Importantly, the same research group has shown that other retroviruses such as murine leukemia virus (MLV) and simian immunodeficiency virus (SIV) are also inhibited by HERC5³⁷⁹. Interestingly, although SIV was inhibited by human HERC5, an ancestral version of HERC5 found in coelacanth fish was unable to inhibit SIV replication, suggesting that the HERC5 gene has evolved to combat lentiviruses in primates³⁷⁹.

1.3.5.4 Role of ISGylation in Ebolavirus replication

Ebola virus infection induces strong expression of both ISG15 and HERC5 starting at 1 day post infection and lasting at least until day 7³⁸⁰⁻³⁸³. Early studies reported that ISG15 over-expression inhibited NEDD4 from ubiquitinating Ebolavirus VP40 and decreased VLP production^{384,385}. This effect was dependent on the inhibition of ubiquitination of the late domain PTPY on VP40. More recent studies by the Barr lab have found that HERC5 inhibits EBOV replication in a pseudotype system (See Chapter 4). This inhibition is dependent on the RLD domain of HERC5 and is correlated with a reduction in viral RNA. Interestingly, this inhibition of EBOV replication was antagonized by the EBOV glycoprotein³⁰⁹.

1.3.5.5 Role of ISGylation in HPV replication

In a proteomic screen to identify ISGylation targets, Durfee et al found that HERC5 ISGylates the L1 capsid protein of HPV16. L1 is the capsid protein of HPV and highly translated during active viral infection. Expression of the ISGylation system significantly reduced viral particle production and infectivity. ISGylation of a small fraction of the total L1 protein led to a dominant inhibitory effect, likely through inhibition of capsid assembly. Since then, no other studies have examined the effect of ISGylation on HPV replication²⁴⁸.

1.3.5.6 Role of ISGylation in Vaccinia virus replication

In mice it was found that Vaccinia virus replication was enhanced in ISG15 knockout cells and was inhibited in cells expressing wildtype levels of ISG15³⁸⁶. This led to the investigation of the antiviral mechanism of ISG15 against Vaccinia virus in ISG15 null cells leading to the discovery that ISG15 deficient cells were more resistant to apoptosis and had impaired phagocytic activity when coming in contact with infected cells³⁸⁷. The effect of ISG15 and HERC5 mediated ISGylation of Vaccinia virus is antagonized by the Vaccinia virus E3 protein³⁸⁸. When E3 was expressed, there was a significant decrease in ISGylated proteins compared to the delta E3 version of the virus. ISGylation of mitochondrial proteins is important for the regulation of oxidative phosphorylation and decreasing reactive oxygen species³⁶⁹. The decrease in ISGylated proteins corresponded with a decrease in ISGylated mitochondrial protein and impaired mitophagy in an infection model. Overall, these studies have demonstrated that control of Vaccinia virus is dependent on the presence of ISG15 and lack of ISGylation, either through ISG15 knockout or deISGylation of proteins by Vaccinia virus E3, leads to enhanced infection kinetics.

1.3.5.7 Role of ISGylation in Kaposi's Sarcoma-Associated Herpesvirus (KSHV) replication

ISG15 and HERC5 were identified as interactors of the KSHV viral homologue of interferon regulatory factor 1 (vIRF1). HERC5 inhibits KSHV in an ISGylation

dependent manner and knockdown of either HERC5 or ISG15 prior to viral reactivation resulted in higher titers of infectious viral particles³⁸⁹. Expression of vIRF1 resulted in a decrease of total protein ISGylation. Later studies suggested that expression of ISG15 may lead to viral latency since knockdown of ISG15 and ISG20 lead to lytic reactivation the virus³⁹⁰. A more recent study implicated CRM1 in the inhibition of KSHV via retention of autophagy adaptor protein p62 (SQSTM1) in the nucleus which led to increased expression of antiviral genes³⁹¹. Interestingly, the RLD domain of HERC5 also inhibits nuclear export in a CRM1 dependent manner²⁴⁶. Although it has not been directly studied, it is possible that in addition to the inhibition of KSHV through ISGylation of cellular and viral proteins, HERC5 inhibits the lytic phase of the virus by a second mechanism involving the CRM1 pathway.

1.3.5.8 Role of ISGylation in Cytomegalovirus replication

Although it has been known for some time that ISG15 and the ISGylation system is induced by cytomegalovirus infection, its role and direct interaction with viral protein was only recently described³⁹². Kim et al demonstrated that knocking down ISG15 or HERC5 lead to a significant increase in viral titers while over-expression of the protein ISGylation system led to decreased viral particle production. Additionally, expression of ISG15 and HERC5 inhibited the viral replication cycle by reducing the expression of viral genes as well as disabling viral budding at the plasma membrane³⁹². Two antagonists of HERC5 and ISG15 were discovered in this study. First, the IE1 protein suppressed ISGylation through a reduction in ISG15 transcription likely through inhibition of STAT2 dependent interferon response activation. Second, UL26 interacts with ISG15 and HERC5 to inhibit protein ISGylation^{392,393}. UL26 has been implicated as a major regulator of the innate immune response against HCMV. Tegument delivered UL26 can limit the induction of ISG expression³⁹⁴. Additionally, the pUL50 protein binds to and is involved in the downregulation of UBE1L resulting in decreased global ISGylation³⁹⁵. Much of the research into cytomegalovirus infection and its inhibition by HERC5 and ISG15 have focused on the antagonism of the antiviral effects by HCMV proteins however little is known about the specific effect of ISGylation on viral proteins

other than it has a dominant inhibitory effect. Further studies are needed to elucidate the precise mechanism of inhibition by HERC5 and ISG15.

1.3.5.9 Role of ISGylation in Zika Virus replication

Upon Zika virus infection HERC5 and ISG15 are induced 481-fold and 28-fold, respectively, over the uninfected control in primary human brain microvascular endothelial cells. As the infection progresses HERC5 levels drop almost 10-fold while ISG15 levels increase another 60-fold compared to the control by day 9 of the infection³⁹⁶. The consequence of increased expression of HERC5 and ISG15 is somewhat controversial with both proviral, and antiviral effects having been proposed^{359,397–399}. The discrepancy in the results may be due to either the timeframe of the experiments or the cell type used. Wang et al³⁵⁹ performed the experiments in a 24-hour infection time frame whereas both this study and others showed that induction of ISG15 increased with time and correlated with a decrease in viral protein at 96-hours post infection. It is clear that additional studies in primary cell lines with longer periods of follow up are needed to tease out the true effect of ISG15 and HERC5 in Zika Virus infection.

Based on the previous work by the Barr lab and the above mentioned finding we sought to further investigate the small HERC family of proteins with a specific focus on their structural and functional contribution to the innate immune system. Our hypothesis is that the small HERC family of proteins have evolved through gene duplication events to become important interferon induced antiviral proteins, which function to inhibit the activity of diverse RNA viruses such as HIV and EBOV. We found that HERC3 and 4 are evolutionarily distant to HERC5 and HERC6 and are not as strongly induced by interferon treatment. Additionally, they did not exhibit strong antiviral activity against HIV-1. Since HERC5 and HERC6 are the small HERC family members exhibiting the strongest antiviral activity, in Chapter 3 we continued to investigate the substitution of an amino acid residue on HERC6 which confers antiviral activity against HIV as strong as that observed with HERC5. We found that HERC6 R10G inhibits the production of infectious particles by a yet unknown mechanism. In Chapter 4, to determine the breadth

of HERC5 as a strongly induced antiviral protein, we investigated the ability of HERC5 to restrict EBOV. We found that HERC5 strongly inhibits EBOV structural protein VP40 in *in vitro* assays through depletion of its RNA. This inhibition was antagonized by EBOV GP. All together these studies advance the knowledge of the small HERC proteins both structurally and functionally and provides additional information about the host protein interactions during viral infection with HIV and EBOV as well as potential targets for drug development.

Chapter 2

2 Evolution-Guided Structural and Functional Analyses of the HERC Family Reveal an Ancient Marine Origin and Determinants of Antiviral Activity

In humans, homologous to the E6-AP carboxyl terminus (HECT) and regulator of chromosome condensation 1 (RCC1)-like domain-containing protein 5 (HERC5) is an interferon-induced protein that inhibits replication of evolutionarily diverse viruses, including human immunodeficiency virus type 1 (HIV-1). To better understand the origin, evolution, and function of HERC5, we performed phylogenetic, structural, and functional analyses of the entire human small-HERC family, which includes HERC3, HERC4, HERC5, and HERC6. We demonstrated that the HERC family emerged >595 million years ago and has undergone gene duplication and gene loss events throughout its evolution. The structural topology of the RCC1-like domain and HECT domains from all HERC paralogs is highly conserved among evolutionarily diverse vertebrates despite low sequence homology. Functional analyses showed that the human small HERCs exhibit different degrees of antiviral activity toward HIV-1 and that HERC5 provides the strongest inhibition. Notably, coelacanth HERC5 inhibited simian immunodeficiency virus (SIV), but not HIV-1, particle production, suggesting that the antiviral activity of HERC5 emerged over 413 million years ago and exhibits species- and virus-specific restriction. In addition, we showed that both HERC5 and HERC6 are evolving under strong positive selection, particularly blade 1 of the RCC1-like domain, which we showed is a key determinant of antiviral activity. These studies provide insight into the origin, evolution, and biological importance of the human restriction factor HERC5 and the other HERC family members. This chapter was published in *Journal of Virology* Vol. 92, No. 13 on June 13, 2018 (see Appendix 2 for permissions).

2.1. Introduction

Vertebrates possess multiple defense mechanisms to inhibit the replication of viruses. This defense system is largely composed of specialized hematopoietic cells that react

nonspecifically to pathogens (innate immunity), an antibody-dependent and cell-mediated response (adaptive immunity), and core cellular effector proteins called restriction factors (intrinsic immunity). Restriction factors are considered to be the front line of defense against viral infection, since their activity typically does not require virus-triggered signaling or intercellular communication¹. The importance of intrinsic immunity in vertebrates is highlighted by the evolutionarily ancient origin and broad antiviral activity of restriction factors, such as bone marrow stromal antigen 2 (BST-2)/tetherin². Other restriction factors, such as apolipoprotein B mRNA-editing enzyme catalytic polypeptide-like 3G (APOBEC3G) and tripartite motif protein 5 alpha (TRIM5 α), are unique to placental mammals and appear to play more specialized antiviral roles by targeting a more limited range of viruses, largely retroviruses³⁻⁸.

Interferon-stimulated gene 15 (ISG15) and/or its conjugation to newly translated proteins (referred to as ISGylation) exhibits broad antiviral activity toward evolutionarily diverse viruses, including those belonging to the families Retroviridae, Orthomyxoviridae, Flaviviridae, Togaviridae, Herpesviridae, Poxviridae, Arteriviridae, and Pneumoviridae⁹⁻³¹. The main cellular E3 ligase responsible for ISGylation activity is “homologous to the E6-AP carboxyl terminus (HECT) and regulator of chromosome condensation 1 (RCC1)-like domain-containing protein 5” (HERC5), an interferon (IFN)-induced restriction factor that has evolved under strong positive selection in vertebrates^{20-23,32-36}. HERC5 belongs to a subfamily of four small HERC proteins, HERC3 to -6. Although referred to as “small,” the small HERC proteins are ~116 kDa in size, each containing a single amino-terminal RCC1-like domain and a carboxyl-terminal HECT domain. The small HERCs are classified as E3 ligases due to the presence of their HECT domains and their ability to conjugate ubiquitin or ubiquitin-like molecules to proteins³²⁻³⁴. Although the biological functions of the small-HERC family have not been fully defined, their E3 ligase activities have been implicated in a variety of biological processes, such as protein degradation, cell signaling, spermatogenesis, tumor suppression, and antiviral defense (reviewed in reference³⁷).

By virtue of their RCC1-like domains, HERCs also belong to the phylogenetically widespread RCC1 superfamily of proteins^{38,39}. The prototypical member of this superfamily is RCC1, characterized by the presence of seven repeats of 51 to 68 amino acids that assume a 7-bladed β -propeller structure. RCC1 is localized in the nuclei of eukaryotic cells and activates the GTPase Ras-related nuclear (Ran) protein⁴⁰. RCC1 maintains a >1,000-fold higher level of RanGTP in the nucleus than in the cytoplasm, which is critical for Crm1-dependent nuclear export of macromolecules^{41,42}. We previously showed that human HERC5 inhibits the Crm1-dependent nuclear export of incompletely spliced human immunodeficiency virus type 1 (HIV-1) RNA, resulting in a severe reduction in the level of intracellular HIV-1 Gag protein and production of virus²². This mechanism is independent of its E3 ligase activity. Blade 1 of the 7-bladed β -propeller RCC1-like domain structure of HERC5 was critical for this inhibition and contained numerous residues predicted to be evolving under positive selection, identifying the region as a potential key antiviral interface between HERC5 and viruses²². Thus far, antiviral activity has been demonstrated only for human HERC5 and its functional homolog in mice, HERC6^{20,21,23,32–36}. Here, we investigate the evolutionary origins and antiviral activities of the HERC family members, providing a better understanding of the role these proteins play in intrinsic immunity.

2.2. Results

2.2.1. The small-HERC gene family has an ancient marine origin more than 595 million years ago.

With the sequencing of many evolutionarily diverse vertebrate and mammalian genomes, we can approximate the emergence and divergence of gene families throughout evolution. We analyzed the most recent genome assemblies (UCSC Genome Browser [<https://genome.ucsc.edu>]) and NCBI gene and protein sequence databases for the presence of small HERC gene members. The oldest small-HERC member is HERC4, which is present in one of the only surviving lineages of jawless fish, sea lampreys (originating ~595 million years ago [mya])⁴³. To better understand the evolution of the

small-HERC family, we investigated the emergence and divergence of HERC genes in evolutionarily diverse vertebrates. The elephant shark is among the oldest and most slowly evolving jawed vertebrates and has accumulated a small number of chromosomal rearrangements⁴⁴. This allowed us to look for evidence of gene expansion at an early point in vertebrate evolution (~476 mya)⁴³. A single copy of HERC4 and multiple copies of HERC3 are present in elephant sharks. Two copies of HERC3 are located immediately adjacent to HERC4, likely representing an early point in vertebrate evolution (~476 to 595 mya), just after the small-HERC family expanded with the duplication and divergence of HERC4 (Figure. 2.1). HERC3 and HERC4 are present in all the jawed vertebrates examined except the platypus, which appears to be the only vertebrate that contains two copies of HERC4. Since the only available assembly for platypus is considered low coverage, future improvements in the assembly are needed to help explain this apparently unique composition of the HERC family in these mammals. Chromosomal rearrangement likely occurred sometime after the divergence of ray-finned fish from cartilaginous fish (~430 mya), giving rise to two different chromosomal HERC loci in most vertebrates, where the HERC3-HERC5-HERC6 locus is flanked by FAM13A and PIGY-PYURF and HERC4 by MYPN and SIRT1 (Figure. 2.1B).

Figure 2.1 Emergence of the small-HERC family

(A) HERC3 (black), HERC4 (red), HERC5 (blue), and HERC6 (green) sequences were searched in genome assemblies using the UCSC Genome Browser (<https://genome.ucsc.edu>) and NCBI gene and protein sequence databases. The presence of HERC orthologs in species is indicated by colored lines. The approximate dates of divergence among the organisms are indicated by the timeline on the left from the perspective of humans, as previously described by Hedges et al.⁴³. The Bayesian tree was obtained from a multiple-sequence alignment of 251 genes with a 1:1 ratio of orthologs in 22 vertebrates, rooted on cartilaginous fish (support was 100% for all clades but armadillo and elephant, with 45%), as described previously⁴⁵. The dashed black lines indicate that no HERC orthologs were identified in the species. The dashed red and blue lines indicate the presence of partial HERC4-like and HERC5-like sequences, respectively. (Adapted from reference 45 with permission of the publisher [Springer Nature].) **(B)** Syntenic relationships of the genomic contexts of the small-HERC loci in evolutionarily diverse vertebrates. Chromosome numbers are indicated on the left of each locus. Un, unplaced scaffold.

The HERC family expanded further after the divergence of cartilaginous fish (~430 mya), with the emergence of HERC6, which is present in most jawed vertebrates with an apparent absence in platypus and some fish (e.g., zebrafish) and bird (e.g., chicken, turkey, and zebra finch) species (Figure. 2.1). The last expansion of the HERC family occurred after the divergence of ray-finned fish (~413 mya), with the likely duplication of HERC6, giving rise to HERC5 (Figure. 2.1B). HERC5 is present in the coelacanth, one of the earliest predecessors of tetrapods, and appears to have been lost in some species of frogs, birds (e.g., chicken), metatherian (marsupial) mammals (e.g., opossum), and rodents (e.g., mouse) (Figure. 2.1)^{43,45}. A partial HERC5-like gene was identified in turkey, and a partial HERC4-like gene was identified in turkey and finch, possibly indicating erosion of the gene family in birds. In species that appear to have lost HERC orthologs, we cannot rule out the possibility that the orthologs are present but were

missed due to low sequence homology and/or incomplete genome annotation. Together, these findings indicate that the small-HERC family has an ancient marine origin at least 595 mya, before the emergence of jawed vertebrates, and has undergone chromosomal rearrangement, gene duplication, and potential gene loss events during vertebrate evolution.

2.2.2. Evolutionarily distant RCC1-like domains and HECT domains are well conserved.

Phylogenetic analysis of HERC sequences showed segregation of the small HERC genes into four major clusters consisting of HERC3, HERC4, HERC5, and HERC6 (Figure 2.2A). Most HERC orthologs have high sequence homology, ranging from ~70 to 100% amino acid identity, whereas most HERC paralogs have low homology, ranging from ~34 to 57%. Notably, coelacanth and lizard HERC5 sequences clustered on their own, showing more sequence similarity to HERC6 genes than to other HERC5 genes, possibly indicating that these genes are actually HERC6 or a hybrid of HERC5 and HERC6. Similar tree topologies regarding the main branching were predicted using several tree-generating algorithms (maximum likelihood, minimal evolution, unweighted pair group method using average linkages [UPMGA], and neighbor-joining methods). Consistent with the approximate emergence times of the small-HERC family members shown in Figure 2.1, HERC4 is the oldest of the HERC paralogs, followed by HERC3, HERC6, and then HERC5.

Figure 2.2 Molecular evolution of the small HERC family

A) Molecular phylogenetic analysis using the maximum likelihood method. The evolutionary history was inferred by using the maximum likelihood method based on the JTT matrix-based model⁴⁶. The bootstrap consensus tree, inferred from 100 replicates, was taken to represent the evolutionary histories of the taxa analyzed. Branches corresponding to partitions reproduced in less than 50% of the bootstrap replicates were collapsed. The percentages of replicate trees in which the associated taxa clustered together in the bootstrap test (100 replicates) are shown next to the branches. Initial trees for the heuristic search were obtained automatically by applying neighbor-joining and BioNJ algorithms to a matrix of pairwise distances estimated using a JTT model and then selecting the topology with a superior log likelihood value. The analysis involved 91 amino acid sequences. All positions containing gaps and missing data were removed. There was a total of 433 positions in the final data set. Evolutionary analyses were conducted in MEGA7 (83). H3, HERC3; H4, HERC4; H5, HERC5; H6 HERC6. **(B to F)** Evolutionary conservation of HERC RCC1-like domains. **(B to E)** Predicted structures of the RCC1-like domains were generated using 3D-Jigsaw (v2.0). Multiple structural alignments were generated based on the QH structural measure using the program STAMP, a plug-in in the MultiSeq interface of the Visual Molecular Dynamics (VMD) software (v1.9.2). **(F)** Three-dimensional representation of the structural data colored by structural conservation. Each amino acid is colored according to the degree of conservation within the alignment: blue, highly conserved; white, somewhat conserved; and red, very low or no conservation. The structure-based cladogram was derived from sequence and structural alignments of the predicted tertiary structures of multiple mammalian HERC RCC1-like domains. **(G to K)** Evolutionary conservation of HERC HECT domains. **(G to J)** Three-dimensional representations of the predicted HECT domain structural data colored by structural conservation. **(K)** Structure-based cladogram derived from sequence and structural alignments of the predicted tertiary structures of multiple mammalian HERC HECT domains.

The small HERCs are believed to have arisen from a gene fusion event between an RCC1-like domain and a HECT domain⁴⁷. Although the approximate date of this event is

unknown, the presence of HERC4 in jawless fishes (e.g., lampreys) suggests that the fusion event occurred more than 595 mya. Typically, the primary amino acid sequences of RCC1-like domains have low sequence homology in the RCC1 superfamily; however, their tertiary structures are highly conserved^{38,39}. To assess how conserved the predicted tertiary structures are among the different small-HERC members, we generated a phylogenetic tree based on the QH structural measure derived from alignment of the predicted tertiary structures of RCC1-like domains (Figure 2.2B to F). The models were predicted using 3D-Jigsaw v2.0 (<https://bmm.crick.ac.uk/~populus/>) and showed that each of the RCC1-like domains of HERC3 to -6 adopted the characteristic β -propeller structure of the superfamily, despite their low sequence homology⁴⁸⁻⁵². Alignment of the structures was carried out using the program Structural Alignment of Multiple Proteins (STAMP), which is a tool for aligning protein sequences based on their three-dimensional structures⁵³. The STAMP algorithm minimizes the C α distance between aligned residues of each molecule by applying globally optimal rigid-body rotations and translations. STAMP analysis revealed that the RCC1-like domains of the HERC orthologs are well conserved overall, with HERC3 and HERC4 being the most conserved (Figure 2.2B to F). Several paralogs showed greater similarity to each other than to their orthologous counterparts (e.g., lizard HERC4 and human HERC6). Chimpanzee HERC3 differed substantially from the other HERCs in that it lacks blade 3 of the β -propeller. Notably, the amino-terminal blade 1 of each RCC1-like domain is the least conserved region and adopts a more extended conformation than the other blades.

Analysis of the predicted HECT domain structures showed that they all adopted the typical bilobial structure of HECT domains (Figure 2.2G to K). STAMP analysis showed that the different orthologs are well conserved overall, with HERC3 and HERC4 being the most conserved. Some HERC5 and HERC6 paralogs shared more similarity to each other than to their respective orthologs. Notably, coelacanth and mouse HERC6 proteins were more similar to HERC5 paralogs than to other HERC6 orthologs, potentially indicating conservation in structure and function of these HECT domains (Figure 2.2K). This is consistent with the finding that mouse HERC6 is the functional homolog of

human HERC5; these are the main cellular E3 ligases for ISG15 in mice and humans, respectively. Together, these data show that despite low sequence homology, evolutionarily divergent HERC genes share remarkable similarity in the predicted structures of their RCC1-like domains and HECT domains.

2.2.3. Human HERC3 to -6 differentially inhibit HIV-1 particle production.

Given the remarkable similarity in the predicted structures of the HECT and RCC1-like domains, we asked whether human HERC3, HERC4, and HERC6 inhibited HIV-1 particle production like HERC5. To test the effect on HIV-1 replication of knocking down endogenous HERC protein levels, we first screened different HERC short hairpin RNA (shRNA) constructs for the ability to knock down endogenous HERC mRNA and protein levels. As shown in Figure 2.3A, several of the shRNA constructs knocked down HERC mRNA levels by 2- to 5-fold. For each shRNA construct used, no significant differences in mRNA levels were detected for any of the other related small HERCs, demonstrating specificity (Figure 2.3B). Unfortunately, we were unable to readily measure endogenous levels of HERC proteins using several different commercially available antibodies. This could be due to poor recognition of endogenous HERC proteins by the antibodies and/or tightly controlled cytosolic levels of HERC proteins, as previously observed³⁴. As such, HERC protein knockdown efficiencies of the shRNA constructs were instead determined using exogenously expressed Flag-tagged HERC constructs (Figure 2.3C). shRNAs that knocked down Flag-tagged HERC3, HERC4, HERC5, and HERC6 protein levels by 10.1-, 7.2-, 5.0-, and 3.6-fold, respectively, were used for subsequent experiments.

Figure 2.3 HERC3 to -6 differentially restrict HIV-1 particle production

A and B) HOS-CD4-CXCR4 cells were transfected with a plasmid carrying either scrambled shRNA (control) or shRNAs to each of the different HERCs independently. HERC mRNA levels were measured by qPCR using HERC-specific primers. The average fold changes in HERC mRNA levels (with standard errors of the mean [SEM]) from the results of 3 independent experiments are shown. One-way analysis of variance (ANOVA) and Dunnett's multiple-comparison test with the control were performed. **(C)** 293T cells were first transfected with plasmids carrying HERC shRNA and 24 h later with the respective Flag-tagged HERC constructs. HERC protein levels were measured by quantitative Western blotting (immunoblotting [IB]) using anti (α)-Flag or anti-GAPDH (loading control). The numbers below the blots represent the average fold

changes in HERC protein levels compared to the control cells after densitometric quantification of the Flag-tagged HERC bands. **(D)** HOS-CD4-CXCR4 cells were transfected with pR9 and plasmids carrying either scrambled shRNA (control) or shRNAs to each of the different HERCs independently. Seventy-two hours after transfection, cell lysates and HIV-1 virions in the supernatant were harvested. HIV-1 particle production was measured by quantitative Western blotting using anti-p24CA or anti-GAPDH. **(E)** Average (plus SEM) densitometric quantifications of Pr55Gag (cells) and p24CA (virions) bands. Virions produced from the cells were used to infect the luciferase reporter cell line TZM-bl to measure the number of infectious virions. The average fold changes in relative light units (RLU) from the results of at least 3 independent experiments are shown. **(F and G)** 293T cells were cotransfected with pR9 and pGFP (transfection control) and increasing amounts of either empty vector, pHERC3, pHERC4, pHERC5, or pHERC6. Virions in the supernatant and total cell lysates were subjected to quantitative Western blot analysis using anti-p24CA, anti-eGFP, and anti- β -actin as a loading control. The average (plus SEM) densitometric quantification of p24CA and Pr55Gag levels from Western blot images of virions or cell lysate (3.6 μ g HERC lane) are shown on the right. The values were normalized to β -actin and eGFP levels. **(G)** Virions produced from cells were used to infect the luciferase reporter cell line TZM-bl to measure the number of infectious virions. **(H)** 293T cells were transfected with either empty vector or increasing amounts of plasmids encoding the different HERCs. Twenty hours post-transfection, total RNA was harvested from the cells and subjected to qPCR to measure HERC mRNA levels. Relative fold changes in HERC mRNA compared to the control cells are shown. Statistical significance was determined using one-way ANOVA and Dunnett's multiple-comparison test with the control cells. *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$; ****, $P < 0.0001$.

HOS-CD4-CXCR4 cells were co-transfected with plasmids carrying HERC shRNA and HIV-1 R9 (a full-length replication-competent NL4-3 derivative). After 72 h of

replication (~2 or 3 rounds), quantitative Western blot analysis of cell lysates or virions produced from cells showed that cells knocked down for HERC5 expression exhibited a significant increase in Gag particle production (~8-fold), whereas HERC3, -4, and -6 released modestly more virions into the supernatant than the control cells (~2-fold) (Figure 2.3D). The amount of infectious HIV-1 in the supernatant was also measured by infecting the TZM-bl indicator cell line, which enabled quantitative analysis of HIV-1 using luciferase as a reporter⁵⁴⁻⁵⁸. Cells knocked down for endogenous HERC5 expression failed to inhibit production of infectious HIV-1, whereas cells knocked down for HERC3, HERC4, or HERC6 expression released levels of infectious virions similar to those of the control cells (Figure 2.3E).

To test the effect of increased HERC expression on single-round HIV-1 particle production, human 293T cells, which do not support multiround replication, were co-transfected with plasmids carrying HIV-1 (R9) and either empty vector, HERC3, HERC4, HERC5 or HERC6. As expected, HERC5 potently inhibited HIV-1 particle production (Figure 2.3F). HERC3 or HERC4 also significantly inhibited particle production, but not as potently as HERC5. In contrast, HERC6 modestly inhibited HIV-1 particle production but did not achieve statistical significance. As expected, HERC5 also potently inhibited the production of infectious HIV-1, whereas HERC3, HERC4, and HERC6 modestly inhibited production of infectious HIV-1 (Figure 2.3G). Each transfected HERC construct exhibited robust mRNA expression, although HERC3 and HERC4 levels were less than those of HERC5 and HERC6 (Figure 2.3H). Taken together, these data show that upregulated expression of HERC3 to -6 inhibited HIV-1 particle production and replication to varying degrees, with HERC5 exhibiting the most potent activity and HERC6 the weakest activity. Notably, only endogenous levels of HERC5 significantly inhibited production of infectious HIV-1.

2.2.4. Human HERC3 to -6 differentially inhibit nuclear export of incompletely spliced RNA.

We previously showed that human HERC5 blocked nuclear export of Rev-dependent HIV-1 RNA²². To determine if HERC3, HERC4, and HERC6 also blocked nuclear export of Rev-dependent HIV-1 RNAs, we cotransfected 293T cells with plasmids carrying full-length HIV-1 R9 and either empty vector, HERC3, HERC4, HERC5, or HERC6. A plasmid encoding enhanced green fluorescent protein (eGFP) was also cotransfected to serve as a transfection control. Total RNA was harvested from the total cell extract or the cytoplasmic extract only and subjected to quantitative PCR (qPCR) with primers specific for either Gag (unspliced HIV-1 genomic RNA), Rev (fully spliced RNA), β -actin (loading control), or eGFP. Each of the small HERC proteins exhibited significant reductions in the amount of HIV-1 genomic RNA present in the cytoplasm, with HERC5 exhibiting the strongest activity (Figure 2.4A). In contrast, no significant reductions in the export of fully spliced HIV-1 transcripts were observed (Figure 2.4B).

Figure 2.4 HERC3 to -5 inhibit cytoplasmic accumulation of unspliced HIV-1 RNA.

A and B) 293T cells were cotransfected with pR9 and peGFP (transfection control) and either empty vector, pHERC3, pHERC4, or pHERC5. Forty-eight hours after transfection, total RNA was extracted and reverse transcribed into cDNA from whole-cell lysates or from the cytoplasmic fraction only. Quantitative PCR was performed on each fraction using primers specific for unspliced HIV-1 genomic RNA (e.g., Gag), fully spliced RNA (e.g., Rev), β -actin (loading control), or eGFP (transfection control). The proportion of unspliced or fully spliced HIV-1 RNA in the cytoplasmic fraction compared to the total amount of HIV-1 RNA (nuclear plus cytoplasmic) was determined for control cells and cells expressing HERC after normalization to β -actin and eGFP levels. The fold changes in copy numbers relative to control cells are shown. The data shown represent the averages (plus SEM) from the results of four independent experiments. **(C)** Schematic depicting the different Gag-Pol constructs used in the experiment shown in panel D. CMV, cytomegalovirus; SA, splice acceptor; SD, splice donor. **(D)** 293T cells were cotransfected with increasing amounts of plasmids encoding HERC3, HERC4, or HERC5 and either Rev-dependent GagPol-RRE (plus pRev) or Rev-independent GagPol-4 \times CTE. The total DNA transfected was kept equal with the empty-vector plasmid. Gag levels within the cell lysates were analyzed by quantitative Western blotting using anti-p24CA and anti- β -actin as a loading control. **(E and F)** Densitometric quantification of Pr55Gag bands from the lanes containing the largest amount of each HERC in the Western blots from panel D was performed. Shown are the average fold changes (plus SEM) in Pr55Gag levels relative to the empty-vector control after normalization to β -actin levels. Statistical significance was determined using ANOVA with Dunnett's multiple-comparison test. *, $P < 0.05$; **, $P < 0.01$, ***, $P < 0.001$; ns, not significant.

To further support this finding, we tested the abilities of the small HERCs to inhibit Gag expression from Rev-dependent (e.g., GagPol-RRE) and Rev-independent (e.g., GagPol-4 \times CTE) constructs, as previously described^{22,59}. HIV-1 Rev promotes nuclear export of incompletely spliced HIV-1 mRNAs by binding to a specific cis-acting element called the Rev-response element (RRE) located within an HIV-1 intron (Figure 2.4C). HIV-1

mRNA containing four copies of the Mason-Pfizer monkey virus constitutive export element (4×CTE) in place of the RRE is not dependent on Rev for nuclear export and thus serves as a Rev-independent control⁶⁰. Successful export of incompletely spliced RNA can be assessed by Western blotting for Gag protein expression. 293T cells were cotransfected with a plasmid encoding Rev and increasing concentrations of plasmids encoding HERC, with or without pGagPol-RRE or pGagPol-4×CTE. As shown in Figure 2.4D and E, each of the small HERCs differentially inhibited nuclear export of Rev-dependent RNA, where HERC5 exhibited the highest level of inhibition and HERC6 the weakest inhibition. In contrast, none of the HERCs significantly inhibited nuclear export of Rev-independent RNA (Figure 2.4D and F). Together, these findings indicate that the small-HERC members differentially inhibit nuclear export of Rev-dependent RNAs.

2.2.5. Antiviral activity of HERC5 evolved more than 413 million years ago.

We next asked whether the antiretroviral activity of human HERC5 has an evolutionarily ancient origin. Since the coelacanth was the oldest vertebrate in which we identified HERC5, we tested the ability of coelacanth HERC5 to inhibit HIV-1 virus production. To assess potential virus-specific effects, we also tested the antiviral activity toward another, related nonhuman retrovirus, simian immunodeficiency virus (SIV) (SIVmac239, a full-length rhesus macaque derivative lacking the 5' long terminal repeat [LTR]), which is thought to be at least 32,000 years older than HIV-1⁶¹. For comparison, we included human HERC5 and human HERC6, which exhibited the strongest and weakest anti-HIV-1 activities, respectively. Human 293T cells were cotransfected with plasmids carrying SIVmac239 or HIV-1 R9 and increasing concentrations of either empty vector, coelacanth HERC5, human HERC5, or human HERC6. Forty-eight hours after transfection, virus released into the supernatant was measured by Western blotting. As expected, human HERC5 exhibited strong inhibition, whereas both coelacanth HERC5 and human HERC6 exhibited little inhibition of HIV-1 (Figure 2.5A to C). In contrast, each of the HERCs inhibited SIVmac239 virus production, with human HERC5 being the

most potent (Figure 2.5D to F). Together, these results demonstrate that the antiretroviral activity of HERC5 has an ancient marine origin at least 413 mya and that HERC5 and HERC6 exhibit species- and virus-specific antiviral activity.

Figure 2.5 Coelacanth HERC5 restricts SIV, but not HIV-1, particle production. HERC6 is evolving under positive selection.

293T cells were co-transfected with a plasmid carrying HIV-1 (pR9) (A to C) or SIV (pSIVmac239) (D to F) and increasing amounts of plasmids encoding either coelacanth HERC5, human HERC5, or human HERC6. Forty-eight hours post-transfection, virus released into the supernatant was measured by quantitative Western blotting of Gag proteins using monoclonal anti-p24CA (183-H12-5C) or anti-SIVp17 (KK59). The average relative fold changes (plus SEM) in HIV p24CA or SIV p24CA protein levels compared to the control cells after densitometric quantification of 3 independent Western

blot images are shown. Statistical significance was determined using one-way ANOVA with Dunnett's multiple-comparison test with the control cells. **, $P < 0.01$; ***, $P < 0.001$; ****, $P < 0.0001$.

We previously showed that HERC5, especially blade 1 of its RCC1-like domain, has been evolving under positive selection for >100 million years²². We performed a similar analysis for each of the small-HERC members to determine if the other members of the small-HERC family have been evolving under positive selection. HERC evolution in mammals was evaluated under several standard models of sequence evolution using the Server for the Identification of Site-Specific Positive Selection and Purifying Selection (Selecton) program⁶²⁻⁶⁵. This comprised two nested pairs of models (M8a and M8; M7 and M8), in which the first model of each pair is nested in the second model. The M8 model, but not the M8a or M7 model, allows sites to evolve under positive selection. A nonnested-pair (M8a and MEC) model comparison was also performed. The MEC model differs from the other models in that it takes into account the differences between amino acid replacement rates⁶². The nested models were compared using the likelihood ratio test.

Analysis of 12 evolutionarily diverse HERC sequences using Selecton revealed that HERC6, but not HERC3 and HERC4, is evolving under positive selection (Figure 2.6). Allowing sites to evolve under positive selection (M8) gave a significantly better fit to the HERC6 sequence data than the corresponding model without positive selection (M8a and M7) (Figure 2.6B). The MEC model, which allows positive selection, was compared with the M8a null model, which does not allow positive selection. Comparison of the Akaike Information Criterion (AICc) scores (M8a, 25,806; MEC, 25,557) revealed that the MEC model fits the HERC6 data better than the M8a model. The results of the MEC analysis were projected onto the primary sequence of human HERC6 (Figure 2.6C). Notably, ~23% (23 of 102) of the codons cluster within the first 80 amino acids of the amino terminus of the RCC1-like domain, encompassing blade 1 of its predicted β -

propeller structure. Another ~32% (33 of 102) cluster at the carboxyl terminus of the spacer region (amino acids ~630 to 680). These results show that strong positive selection is operating on HERC6, with a large number of codons in blade 1 of the RCC1-like domain and the carboxyl terminus of the spacer region evolving under positive selection.

Figure 2.6 HERC6 is evolving under strong positive evolutionary selection.

A) Neighbor-joining phylogenetic tree for progressive alignment of 12 different HERC6 species using COBALT for multiple protein sequences. The branch lengths are proportional to the amount of inferred evolutionary change. **(B)** Analysis for positive selection was performed using HERC6 amino acid sequences from human (*Homo sapiens*), chimpanzee (*Pan troglodytes*), gorilla (*Gorilla gorilla gorilla*), marmoset (*Callithrix jacchus*), baboon (*Papio anubis*), squirrel monkey (*Saimiri boliviensis*), gibbon (*Nomascus leucogenys*), horse (*Equus caballus*), sheep (*Ovis aries*), cow (*Bos taurus*), dog (*Canis lupus familiaris*), and cat (*Felis catus*). Evolutionary analysis for positive selection in HERC6 used various models of evolution, where M8 and MEC allowed sites to evolve under positive selection and M7 and M8a did not. L represents the likelihood of the model given the data, p represents the number of free parameters, and N represents the sequence length. The lower the AICC score, the better the fit of the model to the data, and hence, the model is considered more justified. **(C)** Schematic showing the results of a Bayesian analysis approach identifying positively selected sites with a ratio of the number of nonsynonymous substitutions per nonsynonymous site (Ka) to the number of synonymous substitutions per synonymous site (Ks) (Ka/Ks) with a value of >1.5 and a 95% confidence interval larger than 1 and therefore considered statistically significant. The HERC6 reference sequence accession number is NM_017912.3

2.2.6. Blade 1 of the RCC1-like domain of human HERC6 is an important determinant of anti-HIV-1 activity.

Given the evolutionary similarities between human HERC5 and human HERC6, we asked why they differed in their antiviral activities. Since we previously showed that blade 1 of HERC5 is required for its anti-HIV-1 activity and that blades 1 of both HERC5 and HERC6 contain numerous residues evolving under positive selection, we asked if blade 1 of HERC5 can confer antiviral activity on HERC6. We replaced either the entire RCC1-like domain (H6:H5RLD) or blade 1 (H6:H5blade1) from human HERC5 with the corresponding region in human HERC6. We then measured the abilities of these HERC6

mutants to inhibit HIV-1 particle production. As shown in Figure 2.7A, the H6:H5RLD and H6:H5blade1 mutants potently inhibited HIV-1 particle production similarly to wild-type HERC5. This inhibition occurred despite levels of H6:H5RLD and H6:H5blade1 protein expression slightly lower than that of wild-type HERC5 (Figure 2.7B). This result indicates that blade 1 is an important determinant of antiviral activity.

Figure 2.7 Blade 1 of the human HERC5 RCC1-like domain confers potent antiviral activity on human HERC6.

A) 293T cells were cotransfected with pR9, peGFP, and either empty vector, pHERC5, pHERC6, pH 6:H5RLD, or pH6:H5blade1. Forty-eight hours post transfection, virions in the supernatant and total cell lysates were subjected to quantitative Western blot analysis using anti-p24CA or anti- β -actin. Densitometric quantification of p24CA (virions) and Pr55Gag (cells) from the results of three independent experiments is shown beside the blots after normalization to the β -actin loading controls. The error bars indicate SEM. ***, $P < 0.001$; ****, $P < 0.0001$. **(B)** Cell lysates from panel A were subjected to Western blot analysis using anti-Flag, anti-eGFP, or anti-GAPDH. Average densitometric quantification of the HERC bands is shown below the blot after normalization to anti-eGFP or anti-GAPDH from the results of three independent experiments.

2.3. Discussion

We showed here that the small-HERC family has an ancient marine origin, where HERC4 emerged at least 595 mya and expansion of the family occurred sometime after

the divergence of jawed vertebrates from jawless vertebrates (~476 to 595 mya). Elephant sharks are among the oldest and most slowly evolving jawed vertebrates and have accumulated a small number of chromosomal rearrangements⁴⁴. Thus, analysis of their genome allows us to gain insight into the early evolution and expansion of gene families. The presence of a single copy of HERC4 and multiple copies of HERC3 in the elephant shark likely represents an early time in vertebrate evolution when the HERC4 ancestral gene duplicated and evolved into HERC3. Although the evolutionary pressures in vertebrates triggering expansion of the small-HERC family are unknown, it is plausible, given their antiretroviral activity, that this expansion involved retroviruses. Endogenous retroviruses (ERVs) comprise a substantial portion of vertebrate genomes and appear to have an ancient marine origin, with evidence of ERV sequences found in the genomes of elephant shark, coelacanth, and possibly lamprey⁶⁶⁻⁶⁹. A recent panvertebrate comparative genomic analysis showed that retroviruses have an unprecedented capacity for rampant host switching among distantly related vertebrates, undoubtedly exerting substantial evolutionary pressure on their hosts⁶⁹. Pressures like these can trigger antiviral gene duplication and neofunctionalization events in the hosts, allowing them to evolve more rapidly in order to maintain evolutionary dominance over viruses. Several examples where gene duplication/neofunctionalization has given rise to restriction factor families in primates are MX1, IFITM, TRIM5, and APOBEC3^{5,6,70-75}. These genes, including HERC5 and HERC6, exhibit strong signatures of positive selection, which is consistent with repeated exposure to such evolutionary pressures.

An interesting feature of the small-HERC family is the highly conserved topology of the RCC1-like domain, despite limited sequence homology. By allowing numerous amino acid substitutions while maintaining the overall protein configuration and antiviral activity, these HERC proteins may be able to interfere with the binding of diverse viral antagonists. Evidence of such an evolutionary battle lies in the strong signatures of positive selection in both human HERC5 and HERC6, especially blades 1 of their RCC1-like domains, which we have shown to be important determinants of antiviral activity. HERCs are not the only restriction factors likely to have played an important antiviral

role early in vertebrate evolution. BST2/tetherin has also been shown to have an ancient marine origin, emerging >450 mya, before the separation of cartilaginous fish from bony vertebrates². Like the HERC family, the general topology of BST2/tetherin orthologs are also highly conserved despite low sequence homology, and it is the overall protein configuration that is important for its antiviral activity^{2,76,77}. This evolutionary strategy may help BST2/tetherin and HERC proteins maintain evolutionary dominance over viruses.

We observed that some small HERC genes have been lost in some species, most notably birds and rodents. For birds, this is not too surprising, given that their genomes have been subjected to lineage-specific erosion of repetitive elements, large segmental deletions, and gene loss (>1,000 genes), resulting in a smaller repertoire of immune genes than in humans^{78,79}. Although HERC5 and HERC6 are missing in most bird species, HERC3 and/or HERC4 are present. Given their modest antiretroviral activity in humans, it will be interesting to learn if HERC3 and HERC4 play an antiviral role in birds, perhaps compensating for the loss of HERC5 and HERC6. Other potent antiviral restriction factor genes, such as BST2/tetherin, TRIM22, TRIM5, and APOBEC3G, are also notably absent from birds; however, they do possess other members of the BST, TRIM, and APOBEC families, whose antiviral activities remain largely uncharacterized in birds. Rodents also have HERC3 and HERC4 but also possess at least one of the HERC5 and HERC6 genes. For example, mice, rats, and hamsters possess HERC6 but lack HERC5, ground squirrels possess HERC5 but lack HERC6, and guinea pigs possess both HERC5 and HERC6. Since no rodent lacks both HERC5 and HERC6, it is likely that one of these genes has assumed the role of the main cellular E3 ligase for ISG15 in the absence of the other, potentially adding a new antiviral defense for rodents. For instance, this is the case in mice, which possess only HERC6, which encodes the main cellular E3 ligase for ISG15 and serves as a critical antiviral defense mechanism in mice^{80,81}. Our phylogenetic analysis, where we showed that the predicted structures of the HECT domains of mouse HERC6 and human HERC5 (the main cellular E3 ligase for ISG15 in humans) share a high degree of similarity, also supports this finding. One possibility for the loss of

HERC5 or HERC6 in rodents is that retroviruses or other viral pathogens have not provided constant selective pressure to maintain both genes in these species. A similar dynamic history of gene expansion and loss is evident for other restriction factors, such as TRIM22, TRIM5, and BST2/tetherin^{2,7,82}.

As genes duplicate, neofunctionalize, and diverge in response to evolutionary pressures, reliance on the activities of the ancestral genes may diminish, or they may be replaced altogether by their more advantageous descendants (reviewed in reference 83)⁸³.

Therefore, it is not surprising that the human small-HERC family exhibits differential antiviral activity. Despite still possessing antiviral activity when overexpressed *in vitro*, it is unlikely that HERC3 and HERC4 play significant biological roles as antiviral proteins in humans, since they are not IFN induced, nor have they been evolving under positive selection. This role was likely assumed by HERC5 and HERC6 after the divergence of ray-finned fish from cartilaginous fish (~430 mya). However, HERC3 and HERC4 do exhibit differential tissue-specific expression (reviewed in reference 37)³⁷. Therefore, it is possible that HERC3 and HERC4 play more dominant antiviral roles in tissues where their basal expression is already much more elevated, such as in the brain, heart, and stomach for HERC3 and the brain, lung, and testis for HERC4. Moreover, species such as elephant shark, coelacanth, and platypus that contain duplicated copies of HERC3 or HERC4 genes may also express higher levels of these HERC proteins due to increased gene copy numbers. Although we did not test the antiviral activities of other evolutionarily diverse HERC3 or HERC4 proteins, our phylogenetic analyses demonstrated that the HECT and RCC1-like domains of these proteins show remarkable structural similarity to their human counterparts, which do exhibit antiviral activity at elevated levels. It will be interesting to determine if the antiviral function of HERC3 and HERC4 is conserved in these ancient vertebrates, before the emergence of HERC5 and HERC6.

Interactions between host antiviral proteins and their viral-protein targets can be a critical requirement for their antiviral activity. When viral proteins mutate to evade such

interactions, the antiviral protein frequently develops rapid amino acid replacements at the protein-protein interface in an attempt to restore those interactions and maintain evolutionary dominance over the virus. HERC5 is known to interact with evolutionarily diverse viral proteins and, like HERC6, is evolving under strong positive selection^{20-23,32,35,36}. Therefore, it is highly likely that these proteins contain one or more protein-protein interaction interfaces between viral and host proteins. Our findings that blade 1 of the RCC1-like domains of HERC5 and HERC6 contain numerous positively selected residues and that these residues are important determinants of antiretroviral activity indicate that blade 1 is likely one such interface. Although there is currently no evidence that retroviruses have driven positive selection of blade 1, it is interesting that blade 1 of HERC5 is sufficient to confer antiretroviral activity on HERC6. It is possible that the topology of blade 1 from HERC5 is such that it promotes interaction with a cellular protein required for activity that blade 1 of HERC6 prevents. However, our finding that wild-type HERC6 potently inhibited SIVmac239, but not HIV-1, in the same cell type suggests that virus-specific differences are more likely to account for the observed differential antiviral activity between HERC5 and HERC6. Additional structure-function studies are needed to differentiate between these possibilities and others.

In conclusion, the small-HERC family has an evolutionarily ancient origin more than 595 mya, with the latest expansion of the family occurring more than 413 mya. We showed that the structural topologies of the HECT and RCC1-like domains are highly conserved despite low sequence homology and that the antiretroviral activity of HERC5 has an ancient marine origin. HERC5 and HERC6 are evolving under strong positive selection, and a patch of positively selected residues in blade 1 of the RCC1-like domain is a strong determinant of antiviral activity. Altogether, our study highlights the potential importance of the HERC family in intrinsic immunity.

2.4. Materials and Methods

2.4.1. Cell lines.

293T cells were obtained from the American Type Culture Collection. HOS-CD4-CXCR4 and TZM-bl cells were from the NIH AIDS Reagent Program. The cells were maintained in standard growth medium (Dulbecco's modified Eagle's medium [DMEM]) supplemented with 10% heat-inactivated fetal bovine serum (FBS), 100 U/ml penicillin, and 100 µg/ml streptomycin at 37°C with 5% CO₂.

2.4.2. Analyses of sequences and synteny.

The MEGA 7.0 package was used for phylogenetic analysis⁸⁴. The amino-terminal end of the small HERCs varies in length among the different members and was not included for phylogenetic analysis. The first 30 amino acids were omitted from HERC3 and HERC4 and the first 23 amino acids from HERC5 and HERC6. Accession numbers used are listed in Table 1.

Table 1: Accession numbers used for analyses of sequences and synteny

Protein	Species	Accession Number
HERC3	<i>Homo sapiens</i> (human)	NP_055421.1
	<i>Gorilla gorilla gorilla</i> (gorilla)	XP_004039158.1
	<i>Pan troglodytes</i> (chimpanzee)	XP_517337.3

2.4.4. Positive selection.

Positive-selection analysis was performed as previously described²². HERC sequences were aligned, and a phylogenetic tree was generated using COBALT (constraint-based alignment tool) (<http://www.ncbi.nlm.nih.gov/tools/cobalt/>)⁸⁵. The following HERC sequences were obtained from GenBank: for HERC3, *Homo sapiens* (human) (NP_055421.1), *Gorilla gorilla gorilla* (gorilla) (XP_004039158.1), *Pan troglodytes* (chimpanzee) (XP_517337.3), *Nomascus leucogenys* (gibbon) (XP_003265945.1), *Papio anubis* (baboon) (XP_003898995.1), *Saimiri boliviensis boliviensis* (squirrel monkey) (XP_003924058.1), *Callithrix jacchus* (marmoset) (XP_002745644.1), *Bos taurus* (cow) (NP_001077132.1), *Ovis aries* (sheep) (XP_004009758.1), *Felis catus* (cat) (XP_003985228.1), *Canis lupus familiaris* (dog) (XP_535653.3), *Ailuropoda melanoleuca* (giant panda) (XP_002913643.1), and *Equus caballus* (horse) (XP_001496703.3); for HERC4, human (NP_071362.1), gorilla (XP_004049535.1), chimpanzee (XP_001167753.1), gibbon (XP_003258260.1), baboon (XP_003903924.1), squirrel (XP_003928728.1), marmoset (XP_002756356.1), cow (NP_001070362.2), sheep (XP_004021455.1), dog (XP_849808.1), panda (XP_002913788.1), and horse (XP_001503636.1); for HERC5, human (NP_057407.2), chimpanzee (XP_003310459.1), gorilla (XP_004039179.1), marmoset (XP_002745648.1), baboon (XP_003898997.1), squirrel monkey (XP_003924055.1), gibbon (XP_003265940.1), horse (XP_001915115.2), giant panda (XP_002913645.1), sheep (XP_004009762.1), cow (NP_001095465.1), dog (XP_535652.3), and cat (XP_003985249.1); for HERC6, human (NP_060382.3), gorilla (XP_004039178.1), chimpanzee (XP_001160851.1), gibbon (XP_003265938.1), baboon (XP_003899001.1), squirrel (XP_003924053.1), marmoset (XP_002745681.1), cow (NP_001179573.1), sheep (XP_004010096.1), cat (XP_003985250.1), dog (XP_851549.1), and horse (XP_001494887.1). At least 2 independent sequences were available for human, sheep, baboon, marmoset, gibbon, and squirrel monkey. The following sequences were not independently validated: cat, dog, cow, horse, sheep, and giant panda. The identification of site-specific positive selection and purifying selection was generated using the Selecton server

(<http://selecton.tau.ac.il/index.html>). The HERC5 phylogenetic tree was used in the Selecton analysis. Nested pairs of models (M8a and M8; M7 and M8) and a nonnested pair (M8a and MEC) were compared using the likelihood ratio test implemented in the Selecton program.

Plasmids, transfections, antibodies, and Western blotting.

2.4.4.1. Plasmids.

Plasmids encoding Flag-tagged HERC3, HERC4, HERC5, and HERC6 were created by first PCR amplifying the various HERC coding regions from their respective templates (as described above) using the primers in Table 3 rows 1 to 4. The amplified products were then cloned into p3xFLAG-CMV10 using the following restriction enzymes: for HERC3, EcoRI and KpnI; for HERC4, EcoRI and XbaI; for HERC5, BglII and BamHI; and for HERC6, BglIII and EcoRV. The resulting plasmids were named pHERC3, pHERC4, pHERC5, and pHERC6.

To generate pH6:H5RLD, the HERC5 RCC1-like domain was PCR amplified from pHERC5 using the primers in Table 3 row 5. The backbone of pHERC6 was PCR amplified using the primers in Table 3 row 6. The two amplified fragments were cloned using the fast cloning technique⁸⁶.

To generate pH6:H5blade1, blade 1 of HERC5 (amino acids 1 to 100) was PCR amplified from pHERC5 using the primers from Table 3 row 7. The backbone of pHERC6 was PCR amplified using the primers from Table 3 row 8. The two amplified fragments were cloned using the Gibson cloning technique per the manufacturer's instructions (New England Biolabs).

pHERC3- Δ RLD, pHERC4- Δ RLD, pHERC6- Δ RLD, pHERC3-C1018A, pHERC4-C1025A, and pHERC6-C985A were generated similarly, using the primers from Table 3 row 9 to 14 respectively. pHERC5- Δ RLD and pHERC5-C994A were generated previously (86).

The promoterless empty-vector plasmid pGL3, p3xFLAG-CMV10, and peGFP were obtained from Promega, Sigma, and Clontech, respectively. pLKO.1/scrambled shRNA and pLKO.1/HERC5 shRNA were previously described^{22,23}. The following pLKO.1 shRNA constructs were obtained from Dharmacon: HERC3-#1 (TRCN0000000291), HERC3-#3 (TRCN0000000293), HERC4-#4 (TRCN0000034302), HERC6-#2 (TRCN0000160017), and HERC6-#3 (TRCN0000160044). The coding regions of HERC3, HERC4, HERC5, and HERC6 were obtained from the following sources: HERC3 (NM_014606.2), HERC6 (NM_017912.3)⁸⁷, and HERC5 (NP_057407.2)³³. HERC4 (NM_015601.3) was isolated from HeLa cells by first reverse transcribing total RNA and then PCR amplification of cDNA using the primers in Table 3 row 15. All the constructs were verified by sequencing. Transfections were performed using Lipofectamine 2000 (Invitrogen) according to the manufacturer's instructions unless otherwise indicated. Cotransfections of HERC plasmids with pR9 were performed at a ratio of 10:1 unless otherwise noted. Standard Western blot analyses were performed as previously described²². Densitometric analysis was performed using ImageJ 1.43u software 64-bit version (NIH).

For the construction of pSIVmac239 (pREC_nfl_SIV239), the SIVmac239 Spx vector was obtained from the NIH AIDS Reagent Program. We previously constructed pREC_nfl_HIV and pCMV_cplt vectors for *Saccharomyces cerevisiae*-based cloning of diverse HIV-1 strains⁸⁸. We developed a similar method for SIV cloning. To generate pREC_nfl_SIV239, the 5' half of the HIV genome in the pREC_nfl_HIV vector was first replaced with URA3 and then with the 5' half of the SIV239 genome through the yeast recombination technique described below. Yeast colonies were selected on C-leu plates supplemented with uracil but lacking leucine for selection of pREC_nfl_HIV Δ 5'HIV/URA3 and on C-leu supplemented with 5-fluoro-1,2,3,6-tetrahydro-2,6-dioxo-4-pyrimidine carboxylic acid (5-FOA) for selection of pREC_nfl_5'SIV239/3'HIV. C-leu plates allow growth only when a plasmid containing the leucine gene is transformed into the yeast. The 3' half of SIV239 was introduced using the same procedure to form the vector pREC_nfl_SIV239; this vector contains

nearly the full-length SIV239 genome and lacks the 5' repeat (R) and unique (U5) regions. Approximately 95% of the FOA-resistant yeast colonies harbored pREC_nfl_SIV239. A crude yeast lysate was then used to transform bacteria and to amplify these ampicillin-resistant DNA plasmids for purification, as described previously⁸⁸. For yeast recombination, *S. cerevisiae* Hanson (MYA-906) (MAT α ade6 can1 his3 leu2 trp1 URA3) was obtained from the American Type Culture Collection (ATCC). The yeast was grown at 30°C in appropriate medium (yeast extract peptone dextrose [YEPD] or complete [C] minimal medium C-LEU-URA3, C-LEU, or C-LEU/5-FOA), depending on the cloning step. Transformations/recombinations were performed using the lithium acetate (LiAc) method. Briefly, the linearized vector DNA (~1 μ g) and PCR product (~3 μ g) were added to competent cells at a 1:3 ratio, along with 50 μ g of single-stranded salmon sperm carrier DNA (BD Biosciences/Clontech, Palo Alto, CA) and sterile polyethylene glycol (50%)-TE (10 mM Tris-Cl, 1 mM EDTA)-LiAc (100 mM). Following agitation for 30 min at 30°C, the yeast was heat shocked at 42°C for 15 min and plated on C-leu agar plates containing the appropriate selection.

2.4.4.2. Antibodies.

The following reagents were obtained through the NIH AIDS Research and Reference Reagent Program, Division of AIDS, NIAID, NIH: HIV-1 p24 monoclonal antibody (183-H12-5C) from Bruce Chesebro and Kathy Wehrly and anti-SIVmac p17 monoclonal antibody (KK59) from Karen Kent and Caroline Powell. Anti-FLAG and anti-hemagglutinin (HA) (clone 3F10) were purchased from Sigma, anti-myc and anti- β -actin were purchased from Rockland, anti-eGFP was purchased from Clontech, and anti-GAPDH (glyceraldehyde-3-phosphate dehydrogenase) (clone 6C5) was purchased from EMD/Millipore. Anti-HERC3 (H00008916-B01P), anti-HERC4 (H00026091-A01), anti-HERC5 (H00051191-A01), and anti-HERC6 (H00055008-A01) were purchased from Abnova.

2.4.5. Quantitative PCR.

Total RNA was extracted using the PureLink RNA mini kit (Ambion, Life Technologies). Three micrograms of RNA were reverse transcribed to cDNA using Moloney murine leukemia virus (MMLV) reverse transcriptase and oligo(dT) primers (Life Technologies). Prior to qPCR, the cDNA samples were diluted 1:5 with water. Each PCR mixture consisted of 10 µl of SYBR green master mix, 2 µl of gene-specific primers (1 µl of 10 µM forward primer and 1 µl of 10 µM reverse primer), 5 µl of diluted cDNA, and water to a total volume of 20 µl. For quantification of incompletely and fully spliced HIV RNAs, qPCR was run on the Rotor-Gene 6000 qPCR machine (Corbett Life Science) under the following cycling conditions: 10 min at 95°C and 40 cycles of 10 s at 95°C, 15 s at 60°C, and 20 s at 72°C. The Rotor-Gene 6000 series software (version 1.7) was used to determine the cycle threshold (CT) for each PCR. The gene-specific forward and reverse primer are listed in Table 3 rows 16 and 17. Quantification of endogenous HERC mRNA was run on the QuantStudio5 qPCR machine (Applied Biosystems) under the following cycling conditions: 2 min at 95°C and 40 cycles of 5 s at 95°C, 10 s at 60°C, and 20 s at 72°C. QuantStudio design and analysis desktop software (version 1.4) was used to determine the CT for each PCR. The primers are listed in Table 3 rows 18 to 23. To ensure no carryover of DNA into each total purified RNA sample, 3 µg of the purified RNA was used directly as the template without reverse transcription for qPCR, using the primer sets described above.

2.4.6. Statistical analyses.

GraphPad Prism v6 was used for all statistical analyses mentioned in the text. The P values and statistical tests used are mentioned where appropriate. P values of less than 0.05 were deemed significant.

Chapter 3

3 A single nucleotide polymorphism in the RLD domain of HERC6 impacts its antiviral activity against HIV-1

HERC5 is an interferon induced member of the small HERC family which inhibits replication of evolutionarily diverse viruses including human immunodeficiency virus type 1 (HIV). HERC6, a closely related, member of the same family does not inhibit HIV to the same extent. To better understand the discrepancy between the HIV restriction ability of these two proteins we performed structural analysis and discovered that a single nucleotide polymorphism, where the substitution of an arginine at position 10 for a glycine, can alter the theoretical folding of HERC6. This SNP enhanced its ability to inhibit the infectivity of HIV. While most of the human population possesses the defective form of HERC6, people of certain ethnicities possess the active form, which we postulate provides them with an enhanced antiviral defense. In fact, we discovered that possession of the active form of HERC6 is potentially associated with slower disease progression to AIDS in HIV-1-infected individuals in Uganda. Using western blotting, qRT-PCR, and infectivity assays we discovered that overexpression of HERC6-R10G results in less infectious viral particles. To determine the difference between the content of the supernatant released from cells overexpression HERC6 or HERC6-R10G we performed mass spectrometry. We found that the most down-regulated biological processes are viral transcription, viral gene expression, and protein translation-related processes. In our analysis we also noticed a reduction in CADM1 a surface protein which can be involved in viral attachment, however, neutralization of CADM1 did not result in reduced HIV particle infectivity. This study advances the knowledge of the small HERC family and more specifically HERC6, establishing it as an antiviral molecule.

3.1 Introduction

The steps in HIV replication cycle utilize cellular machinery to convert a single infections virion into a multitude of viral particles. Typically, this begins with the attachment of the infectious virions via the interaction of the envelope protein (gp120)

with the CD4 molecule and CCR5 or CXCR4 coreceptor on the surface of CD4+ T cells^{1,2}. Fusion of the viral particle and cell membranes lead to the release of the capsid into the cytoplasm^{1,3-5}. Reverse transcription and uncoating steps are initiated in the cytoplasm and aid in the transport of the HIV pre-integration complex to the nuclear pore where it can enter the nucleus and integrate into the genome^{4,6-8}. Reverse transcription convert a positive sense single-stranded RNA genome into a double-stranded DNA genome which after entering the nucleus integrates into the host DNA^{5,9,10}. Transcription of the HIV genome produces three forms of RNA: 1) a full-length unspliced mRNA that is incorporated into new virions and from which Gag and Gag-pol proteins are translated; 2) a singly spliced mRNA from which gp160, Vif, Vpr and Vpu proteins are translated; and 3) a doubly spliced mRNA from which Nef, Tat, and Rev proteins are translated¹¹⁻¹³. Upon its translation Rev is imported into the nucleus and binds to the Rev Response Element (RRE) forming a complex with RanGTP and CRM1 (also known as exportin1 or XPO1) to shuttle the unspliced viral RNA through the nuclear pore complex into the cytoplasm where it disassembles and RanGTP is hydrolyzed into RanGDP¹⁴⁻¹⁸. The newly translated viral proteins are incorporated into new virions at the plasma membrane commencing with the multimerization of Gag¹⁹. Following multimerization the p6 domain of Gag recruits the endosomal sorting complexes required for transport (ESCRT) proteins which complete membrane fission^{20,21}. A maturation step then occurs where the Gag and Gag-Pol polyproteins are cleaved by the HIV protease (PR) protein to produce infectious particles that can go on to infect neighbouring cells^{19,22,23}.

Sensing of viral infections stimulates an immediate response from the innate immune system triggering the production of interferons and interferon stimulated genes²⁴. From the small HERC family of proteins HERC5 and HERC6 are the only two highly expressed interferon stimulated genes (ISGs). Similar to their other family members, HERC5 and HERC6 both consist of a N-Terminal (RCC1- like) RLD domain linked by a disordered spacer region to the HECT domain²⁵⁻²⁷. The RLD domain is a β -propeller structure consisting of 7 blades and the HECT domain is a C-lobe shape and contains an “active site” cysteine which is involved in the ubiquitination or ISGylation of proteins^{28,29}.

By virtue of its HECT domain, HERC5 is the main E3 ligase for the conjugation of ubiquitin like proteins called interferon stimulated gene 15 (ISG15) to candidate substrates^{27,28,30-33}. ISGylation can have several consequences for the modified protein although the most common is an alteration of function or localization.

Our laboratory and others have clearly established a role for HERC5, and more recently HERC6, in the inhibition of HIV-1 infection^{14,29,34}. HERC5 inhibits HIV-1 replication through two distinct mechanisms. The first involves the RLD domain and inhibits the export of Rev-dependent (unspliced) HIV RNA from the nucleus to the cytoplasm by reducing intracellular levels of RanGTP and/or inhibiting the association of RanGTP with RanBP1¹⁴. The second mechanism of inhibition of HERC5 is dependent on its ISGylation activity and correlated with the ISGylation of Gag^{35,36}. Although ISGylation of Gag results in decreased viral particle production and arrested budding, it is unclear whether this is due to the ability of ISG15 to replace the ubiquitin molecule needed to recruit the ESCRT protein necessary for successful budding, or whether it interferes with Gag multimerization which is essential for virion budding.

Recently, our laboratory discovered that HERC6 has a modest ability to inhibit HIV-1³⁴. However, this ability was largely increased when the RLD domain of HERC6 was replaced with that of HERC5, suggesting that differences in the RLD domains between HERC5 and HERC6 impact anti-HIV activity. Moreover, swapping blade 1 of the RLD domain (first 100 amino acids) from HERC6 with that from HERC5 was sufficient to confer potent inhibition of HIV-1 particle production³⁴. These experiments left many open questions about the contribution of the RLD domain to the anti-HIV activity of the interferon induced HERC proteins. Here we report the discovery of a single nucleotide polymorphism that significantly enhances the ability of HERC6 to inhibit production of infectious HIV-1 particles by a mechanism that potentially disrupts viral transcription and/or viral gene expression.

3.2 Results

3.2.1 Blade 1 of the HERC6 RLD is a determinant of antiviral activity

We previously showed that HERC6 exhibited modest antiviral activity towards HIV-1³⁷. Swapping the HERC6 RLD with the HERC5 RLD, and more specifically the first 100 amino acids (blade 1) of HERC5, conferred potent anti-HIV-1 activity similar to that observed by wild type HERC5. Given the high degree of structural homology between the HERC5 and HERC6 RLDs, we hypothesized that structure-altering amino acid differences in the HERC6 RLD result in diminished antiviral activity.

To further characterize the contribution of the HERC6 RLD to its antiviral activity, we first generated a flag tagged RLD domain deletion mutant of HERC6 (Figure 3.1A). For comparison, we also generated a flag tagged RLD deletion mutant of HERC5. No significant differences in the expression of the mutant proteins were observed (Figure 3.1A). Consistent with our previous observations¹⁴, HERC5 lacking its RLD increased both the amount of intracellular Gag protein and viral particles released from cells after 24 hours ($P < 0.05$) (Figure 3.1A and B). Deletion of the HERC6 RLD domain resulted in a significant increase in viral particles released from cells. In contrast with HERC5, expression of the HERC6 RLD domain mutant did not result in an increase in intracellular Gag protein, suggesting that the HERC6 RLD is important for inhibiting a later stage of viral particle production.

To identify potential amino acid determinants of this antiviral activity, we compared predicted three-dimensional structures of the HERC5 and HERC6 RLDs. As shown in Figure 3.1C, the RLDs of both HERC5 and HERC6 assume a β -propeller structure consistent with that of the RCC1 family of proteins³⁴. Interestingly, blade 1 of the HERC5 RLD is more disordered and extends away from the β -propeller structure whereas blade 1 of HERC6 folds back to interact with blade 2 before extending away from the β -propeller. A positively charged arginine residue at amino acid position 10 (R10) and a negatively charged glutamic acid residue at amino acid position 67 (E67) are located at

this point of interaction in the HERC6 RLD, likely contributing to this interaction (Figure 3.1D). To assess the predicted structural significance of these specific residues, we generated mutant HERC6 sequences containing uncharged alanine mutations at positions R10 (H6-R10A), E67 (H6-E67A) or both R10 and E67 (H6-R10A/E67A) using site-directed mutagenesis. Molecular modeling of these RLD mutants containing the R10A, E67A or R10A/E67A mutations predicted that blade 1 would assume a more disordered structure (without interaction with blade 2), similar to blade 1 of HERC5 (Figure 3.1C).

We then tested the functional significance of the HERC6 R10A, E67A or R10A/E67A mutants in inhibiting HIV-1 particle production. For comparison, we also included HERC5:HERC6 RLD and blade 1 swaps where the HERC5 RLD (H6:H5RLD) or the first 100 amino acids of the HERC5 RLD (H6:H5 RLD₁₋₁₀₀) replaced the corresponding region in HERC6. As expected, HERC5 and to a much lesser extent HERC6, inhibited intracellular production of HIV-1 Gag proteins and inhibited production of viral particles (Figure 3.1F and 3.1G). Despite lower levels of intracellular expression, H6:H5RLD, and especially H6:H5RLD₁₋₁₀₀ exhibited increased inhibition of intracellular Gag protein production and viral particle production. H6-R10A, H6-E67A and H6-R10A/E67A modestly increased the ability of HERC6 to inhibit intracellular Gag protein levels and viral particle production after 24 hours. This data suggests that blade 1 of the HERC6 RLD and, potentially, residues R10 and E67 are determinants of HERC6 anti-HIV-1 activity.

A) 293T cells were co-transfected with pR9 (HIV-1) and either, pHERC5, pHERC6, pHERC5 Δ RLD, or pHERC6 Δ RLD. Twenty-four hours post-transfection, virions released into the supernatant and total cell lysates were subjected to quantitative Western blot analysis using anti-flag, anti-p24CA, or anti-GAPDH as loading controls. **B)** Average densitometric quantification (\pm S.E.M.) quantification of the p24CA (virions) and Pr55Gag, p24CA, and flag bands (cells) from four independent experiments is shown. Statistical significance was measured using Students t-test and the Δ RLD proteins were compared with wildtype. **C)** Two different views of the three-dimensional representation of the predicted structural data of human HERC5 and HERC6 RLDs. Each amino acid is colored per the degree of evolutionary conservation with other HERC homologs. **D) Left**, structural alignment of the RLDs of HERC5 (white) and HERC6 (green). **D) Right**, close-up image showing the interaction of the positively charged R10 residue (red ball and stick) and negatively charged E67 residue (blue ball and stick) of the human HERC6 RCC1-like domain. **E)** Two different views of the three-dimensional representation of the predicted structural data of human HERC6 RLDs containing either R10A (HERC6-R10A) or E67A (HERC6-E67A) mutations. Yellow and green circles denote the locations of the R10 and E67 mutated residues respectively. **F)** 293T cells were co-transfected with pR9 (HIV-1) and either empty vector, pHERC5, pHERC6, pHERC6:HERC5 RLD, HERC6:HERC5 RLD1-100, pHERC6:R10A, pHERC6:E67A or pHERC6:R10A/E67A. Twenty-four hours post-transfection, viral particles released into the supernatant and total cell lysates were subjected to quantitative Western blot analysis using anti-p24CA, anti-Flag and anti- β actin as a loading control. **G)** Average densitometric quantification (\pm S.E.M.) of p24CA (virions) and Pr55Gag, p24CA, and HERC expression (Flag) bands (cells) from four independent experiments is shown. Statistical significance was measured using

One-way ANOVA, Dunnett's multiple comparisons test with either control (above the bar) or wildtype HERC6 (indicated by a line). $P > 0.05$, not significant (ns); * $P < 0.05$, ** $P < 0.01$ *** $P < 0.001$, **** $P < 0.0001$

3.2.2 SNP rs111670008 (R10G) is associated with slower disease progression

To determine if residues R10 and E67 of HERC6 have potential clinical relevance for HIV-1 infection, we first analyzed the human SNP database to determine if polymorphisms have been detected at these residues in the human population. Indeed, SNPs are present in the human population at residues 10 and 67 of HERC6 (rs111670008 and rs775530962 respectively). Since rs111670008 contained more information pertaining to its prevalence in the human population, we asked if rs111670008 is associated with HIV-1 disease progression.

The rs111670008 SNP contains an alanine (contig reference) to guanine nucleotide polymorphism, resulting in an arginine to glycine amino acid change. Analysis of the global allele and genotype frequencies showed that the minor allele frequency of the G nucleotide allele is 2.5% with 13.6% heterozygosity with the A allele. The G allele is rare in the African, East Asian, and South Asian populations and most prevalent in the American and European populations (Figure 3.2A). In the uninfected African population, 99.2% of individuals are homozygous for the A allele, resulting in arginine at position 10; whereas 0% are homozygous for the G allele, resulting in glycine. 0.8% of the population is heterozygous for the A and G alleles. After sequencing the genomic DNA region surrounding amino acid residue 10, we calculated the frequency of each allele from 29 HIV-1-infected individuals in a Ugandan cohort who were classified as either rapid, normal, or slow progressors (Figure 3.2B). Sequence analysis of the 29 patient samples yielded no significant difference in the homozygous (A/A) or heterozygous (A/G) allele frequencies between the uninfected population and rapid progressors; however, there was a significant association between the heterozygous (A/G) individuals and slower disease progression to AIDS (dominant model, odds ratio = 157.4, 95% CI = 35.9 to 690.1, $P <$

0.0001) (Figure 3.2B). This data identifies a potential association of the HERC6 SNP rs111670008 with slower disease progression to AIDS in infected individuals in Uganda.

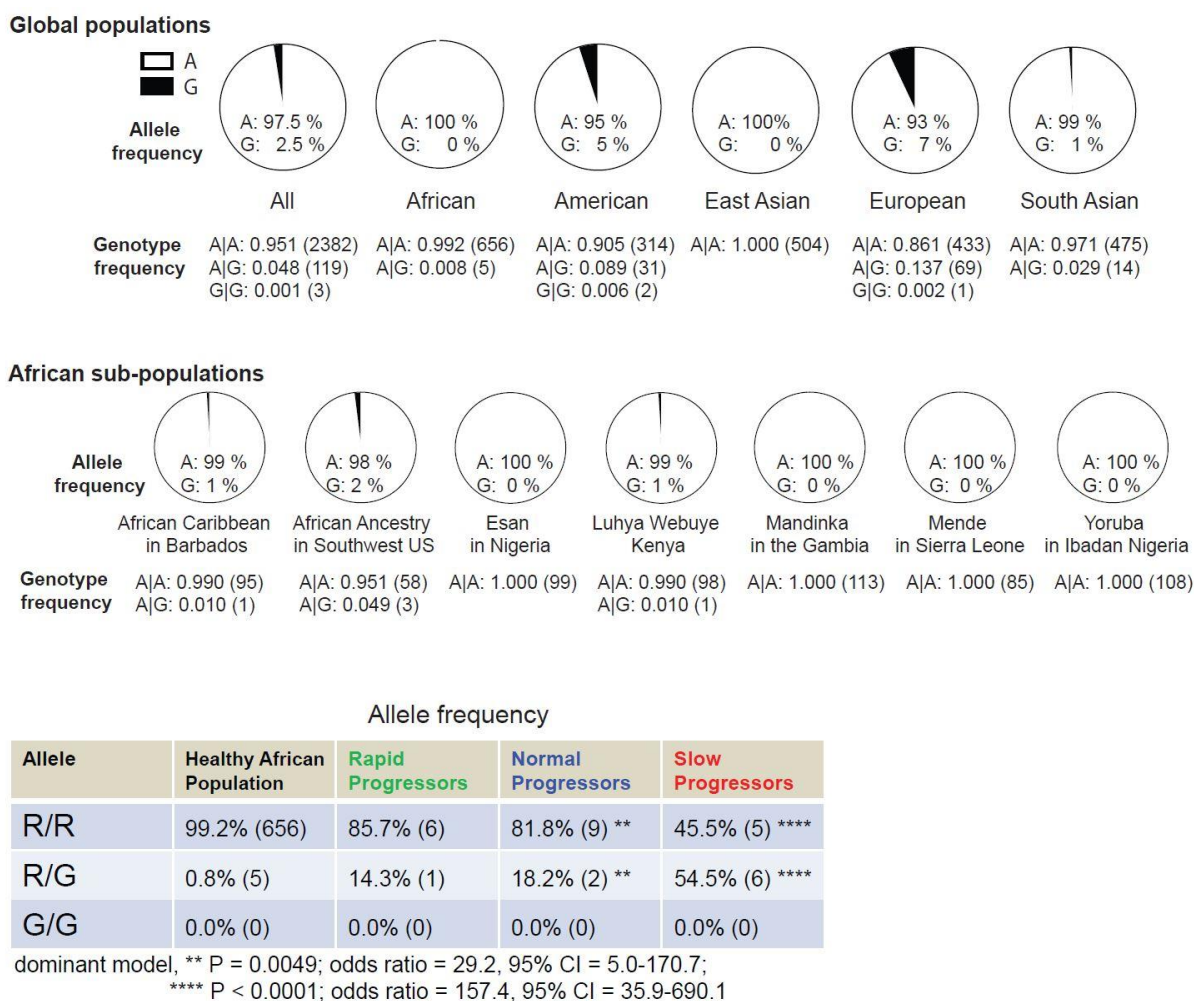

Figure 3.2 HERC6 SNP rs111670008 (R10G) is associated with slower disease progression in a Ugandan cohort of HIV-1-infected individuals.

A) Allele and genotype frequencies of the R10G HERC6 SNP rs111670008 in the global population and African sub-populations. Data was obtained from the 1000 Genomes database. **B)** Genomic DNA encompassing the HERC6 SNP rs111670008 was amplified from genomic DNA isolated from 29 HIV-1 infected

individuals categorized as fast, normal, or slow progressors. The amplified DNA was sequenced to identify the percentages of patients homozygous or heterozygous for the A or G allele at amino acid position 10 of HERC6 and compared to that of the normal healthy African population.

3.2.3 Arginine 10 of blade 1 in the HERC6 RLD is a critical determinant of anti-HIV-1 activity

To further understand the contribution of the rs111670008 SNP (R10G) to the antiviral activity of HERC6, we generated a HERC6 construct bearing the R10G polymorphism and compared its ability to inhibit HIV-1 particle production to that of wild type HERC5 and HERC6. 293T cells were co-transfected with plasmids carrying full-length infectious HIV-1 R9 with or without plasmids carrying flag-tagged HERC5, HERC6 or HERC6-R10G. Twenty-four hours after expression, cells and supernatant were collected and subjected to Western blot analysis. As expected, cells expressing HERC5 and to a lesser extent HERC6 exhibited a significant reduction in intracellular Gag protein and release of viral particles from cells (Figure 3.3A and B). Cells expressing HERC6-R10G exhibited a similar reduction in intracellular Gag protein and release of viral particles from cells as observed with HERC6.

Next, we sought to determine if the R10G SNP impacts the infectivity of virions produced from cells. HOS-CD4-CXCR4 cells, which support robust HIV-1 replication, were co-transfected with pR9 (HIV-1) and either empty vector, flag-tagged pHERC5, pHERC6 or pHERC6-R10G. Seventy-two hours post-transfection, supernatant containing released viral particles were used to infect the luciferase reporter cell line HeLa TZM-bl to measure the level of infectious virions. As previously observed, HERC5 significantly reduced the infectivity of released HIV-1 virions (Figure 3.3A). In contrast, no significant reduction in infectivity was observed for HERC6. Intriguingly, cells expressing HERC6-R10G significantly inhibited the release of infectious virions to a similar degree as HERC5 (Figure 3.3C).

To better understand how HERC6-R10G inhibits the infectivity of HIV-1 virions, we asked if viral RNA levels were affected by HERC6-R10G expression. HIV-1 RNA was isolated from the supernatant of cells co-expressing HERC5, HERC6 or HERC6-R10G and measured using quantitative RT-PCR (qRT-PCR) (Figure 3.3D). As expected, HERC5 significantly reduced the amount of detectable viral RNA in the supernatant. Conversely, no significant reduction was observed with HERC6 or HERC6-R10G. We previously showed that blade 1 of the HERC5 RLD plays a critical role in blocking the production of infectious HIV-1 particles by inhibiting REV-dependent nuclear export of unspliced HIV-1 RNA, which are exported via the CRM1-dependent nuclear export pathway¹⁴. To determine if the R10G substitution in blade 1 of HERC6 conferred a similar ability, we compared the abilities of HERC5, HERC6 and HERC6-R10G to inhibit the export of unspliced HIV-1 RNA from the nucleus using qRT-PCR. As previously observed¹⁴, HERC5 significantly inhibited the export of unspliced RNA from the nucleus (Figure 3.3E). In contrast, no significant inhibition of nuclear export was observed for HERC6 or HERC6-R10G. As a control, none of the HERC constructs inhibited nuclear export of REV-independent RNA, which are exported via the NXF1/TAP-dependent nuclear export pathway. Together, these data suggest that R10G inhibits the production of infectious HIV-1 particles by a mechanism not involving a reduction in virion RNA levels or by inhibiting nuclear export of HIV-1 RNA.

Figure 3.3 HERC6-R10G reduces the infectivity of viral particles.

A) 293T cells were co-transfected with pR9 (HIV-1) and either empty vector, flag-tagged pHERC5, pHERC6 or pHERC6-R10G. Twenty-four hours post-transfection, virions released into the supernatant and total cell lysates were subjected to quantitative Western blot analysis using anti-p24CA or anti-GAPDH as a loading control. **B)** Densitometric quantification of the p24CA (virions in the supernatant) and Pr55Gag and p24CA bands (cells) from four independent experiments is shown. Statistical significance is based on One-way ANOVA, Dunnett's multiple comparisons test with either control or wildtype HERC6. $P > 0.05$, not significant (ns); * $P < 0.05$, ** $P < 0.01$ *** $P < 0.001$, **** $P < 0.0001$. **C)** HOS-CD4-CXCR4 cells, which support robust HIV-1 replication, were co-transfected with pR9 (HIV-1) and either empty vector, flag-tagged pHERC5, pHERC6 or pHERC6-R10G. Seventy-two hours post-transfection, supernatant containing released viral particles were used to infect the luciferase reporter cell line HeLa TZM-bl to measure the level of infectious virions. **D)** 293T cells were co-transfected with pR9 (HIV-1) and either empty vector, flag-tagged pHERC5, pHERC6 or pHERC6-R10G. Twenty-four hours post-transfection, viral RNA was isolated from viral particles released into the supernatant and subjected to qRT-PCR. Statistical significance was measured using one-way ANOVA with Tukey's multiple comparisons test. **E)** 293T cells were co-transfected with full-length replication-competent HIV-1 (pR9) and peGFP (transfection control) and either empty vector (control), pHERC5, pHERC6 or pHERC6-R10G. Forty-eight hours after transfection, total RNA was extracted, and reverse transcribed into cDNA from whole cell lysates or from the cytoplasmic fraction only. Quantitative PCR was performed on each fraction using primers specific to unspliced HIV-1 genomic RNA (Gag), fully spliced RNA (Rev), or GAPDH (loading control). The proportion of unspliced or fully spliced HIV-1 RNA in the cytoplasmic fraction compared to total amount of HIV-1 RNA (whole cell) was determined for control cells and cells expressing HERC. Fold-change in copy number relative to control cells is shown for each fraction. Data shown represents the average (\pm SEM) from four independent experiments.

3.2.4 HERC6-R10G alters the protein content of virus-containing particles released from cells

To better understand the contribution of the R10G polymorphism to the antiviral activity of HERC6, we performed mass spectrometry analysis on virus-containing particles released from control cells or cells expressing HERC6 or HERC6-R10G. The relative expression levels of proteins contained in the virus-containing particles were determined and the most significantly identified proteins were compared to the group mean to obtain relative fold changes in expression levels (Figure 3.4A). We used a significant cut-off of 10, a down-regulation cut-off of 0.8-fold change and an up-regulation cut-off of 1.2-fold change from HERC6. As observed in the heatmap in Figure 3.4A, several cellular proteins are significantly upregulated and downregulated in the particles released into the supernatant of control cells. In comparison, particles released from cells expressing HERC6 exhibited contrasting expression of the majority of these proteins (e.g., red versus blue or blue versus red), while some protein levels remained unchanged (e.g., orange versus orange or blue versus blue).

Interestingly, cells expressing HERC6-R10G exhibited strong contrasting protein expression levels when compared to HERC6. The most down-regulated proteins were Ribosomal protein L6, L35, and L18 (RPL6, RPL35, RPL18), ABRA C-Terminal-Like Protein (ABRACL), Nuclear Casein Kinase And Cyclin Dependent Kinase Substrate 1 (NUKS1), HEAT Repeat Containing 6 (HEATR6), Heterogeneous Nuclear Ribonucleoprotein D (HNRNPD), Histone-lysine N-trimethyltransferase SMYD5, Alpha 2-HS Glycoprotein (AHSG), H1.2 Linker Histone(H1-2), and Cell Adhesion Molecule 1 (CADM1). Proteins that are over-represented consist of Calmodulin 1, 2 and 3 (CALM1, CALM2, CALM3), Albumin (ALB), ubiquinol-cytochrome c reductase core protein 2 (UQCRC2), Prohibitin 2 (PHB2), Voltage Dependent Anion Channel 1 (VDAC1), Elongator Acetyltransferase Complex Subunit 2 (ELP2), Heterogeneous Nuclear Ribonucleoprotein U (HNRNPU), Stomatin-Like 2(STOML2), Ribophorin I (RPN1), DEAD-Box Helicase 42 (DDX42), Heat Shock Protein Family A (Hsp70) Member 9 (HSPA9), Nuclear Receptor Binding Protein 1 (NRBP1), ATP Synthase Peripheral Stalk

Subunit D (ATP5PD) and Destrin (DSTN). Interestingly, many of the proteins identified are ribosomal proteins or related to ribosomal processes. Proteins such as ABRACL and DSTN are involved in the regulation of actin filament processes while PHB2, UQCRC2, and ATP5PD are involved in mitochondrial processing.

To better understand the biological processes most effected by HERC6-R10G, we performed gene ontology (GO) analysis of the proteins most under-represented and over-represented compared to HERC6. Calcium processes are among the most up-regulated by HERC6-R10G expression such as detection of calcium ions, detection of chemical stimulus, mitochondrial calcium ion transmembrane transport, negative regulation of calcium ion transmembrane transport, and cytosolic calcium ion transport (Figure 3.4C). The most down-regulated biological processes are viral transcription, viral gene expression, followed by translation-related processes such as co-translational protein targeting to the membrane, protein targeting to the ER, establishment of protein localization to ER, and protein targeting (Figure 3.4D). These results suggest that compared to HERC6, HERC6-R10G disrupts viral gene expression processes.

Given our previous observations that HERC6 expression exhibited a modest effect in inhibiting intracellular Gag levels and production of virus-containing particles compared to the control, we were interested in identifying proteins whose expression levels differed substantially in the HERC6-R10A samples but were relatively similar between the control and HERC6 samples (Figure 3.4A, box 1 and box 2). Figure 3.4A box 1 highlights several protein candidates that are significantly down-regulated in HERC6-R10G compared to the control/HERC6. GO analysis revealed that these proteins are mostly involved in regulation of cytoplasmic translation. Figure 3.4A box2 highlights several protein candidates that are significantly up-regulated in HERC6-R10G compared to the control/HERC6. Notably among this list of proteins is DDX42. DDX42 was recently shown to potently inhibit HIV-1 and other positive-sense RNA viruses by binding viral RNA³⁸. Taken together, these data show that HERC6 R10G expression

alters the protein composition of HIV-1-containing particles released from cells, leading to an increase in proteins known to disrupt virus replication.

293T cells were transfected with pR9 containing plasmid and empty vector (control), pHERC6 or pHERC6-R10G. Forty-eight hours post transfection the samples were processed and analyzed using LC-MS/MS (see methods) **A)** Protein expression profile of the top 150 differentially expressed genes based on z-scores. Box 1 highlights genes which are detected in HERC6 and control samples but not in HERC6-R10G. Box 2 highlights genes which are highly expressed in HERC6-R10G samples but not in HERC6 and control samples. **B)** Volcano plot showing significance and ratio of proteins comparing their abundance in HERC6-R10G to HERC6 samples. Significance cutoff of 13 was used corresponding to a p-value of 0.05. Proteins beyond a ratio of 1.2 and below 0.8 are highlighted in red and blue respectively. **C)** and **D)** the proteins identified in the volcano plot in **B)** were entered into ShinyGo to obtain significant ($FDR \geq 0.05$) upregulated (**C)** and downregulated (**D)** biological processes.

3.2.5 CADM1 neutralization does not affect viral particle infectivity

The proteomic data suggests that HERC6-R10G disrupts viral gene expression and transcriptional processes. To determine if HERC6-R10G produces altered viral protein expression we examined the viral protein detected in the mass spec samples mentioned above (Figure 3.5A). There was a large difference in the amount of Pol and Env when comparing HERC6 and HERC6-R10G to control samples and a slight decrease in Gag levels. The amount of Nef remained relatively unchanged in all samples and Rev was only detectable in the control sample. Additionally, we have not observed a difference in the RNA content within the viral particles released from cells transfected with HERC6-R10G or HERC6 (Figure 3.3 D).

To further understand if there is a single cellular protein responsible for the difference observed in the infectivity of particles produced in HERC6-R10G expressing cells vs HERC6 expressing cells we looked to see if attachment molecules were differentially

expressed. Cell adhesion molecules such as ICAM-1 are actively incorporated into the viral membrane to facilitate the interaction between the virion and the target cells³⁹⁻⁴¹. We noticed that CADM1 is significantly reduced in the HERC6-R10G sample compared to the HERC6 sample. CADM1 is a cell adhesion molecule mostly known for its role in the attachment of human mast cells to fibroblasts, human airway smooth muscle cells and neurons⁴²⁻⁴⁴. To determine if this effects the infectivity of the viral particles we performed a neutralization assay with a monoclonal antibody against the ectodomain (9D2) of CADM1 which is known to inhibit its adhesive function^{42,45,46}. The HIV-1 neutralizing antibody VRC01 was used as a positive control⁴⁷. We found that neutralization of the CADM1 molecule on the surface of viral particles does not influence the infectivity of the particles. This was the case for both the R9 and the NL43 virus particles. Here, we determined that the effect of the R10G SNP on inhibiting particle infectivity is not due to its modulation of the attachment molecule CADM1.

Figure 3.5 Anti-CADM1 antibody is not able to neutralize HIV-1 R9 or NL43 strains

The graph shows the sum of the area for each HIV-1 protein detected. **B)** HeLa TZM-bl cell neutralization assay using CADM1 neutralizing antibody (9D2), isotype control, or VRC01 antibody. Left panel is neutralization percent of R9 virus and right panel is neutralization percent of NL43 virus stocks. Results are representative of three independent experiments

3.3 Discussion

HIV-1 is one of the deadliest, most widespread viruses on earth. Although the advancement of medical treatments significantly extends the life span of those infected, a true cure or even a preventative vaccine has yet to be found. Here, we report the discovery of a novel SNP in the interferon induced HERC6 molecule which contributes

to its antiviral activity against HIV-1. The HERC6-R10G heterozygous allele is over-represented in HIV-1 slow progressors in a Uganda cohort. Although this SNP does not have an effect on the particle production or intracellular levels of Gag protein (Figure 3.3 A and B), on the nuclear export of viral RNA (both spliced and unspliced) (Figure 3.3E), or on the incorporation of viral RNA into viral particles (Figure 3.3.D), it does have a significant effect on the infectivity of the virions produced in cells expressing it. Using mass spectrometry, we examined the differentially expressed proteins in particles produced in cells expressing either wildtype HERC6 or HERC6-R10G. We found that several proteins such as ribosomal protein 6, 18 and 35 as well as CADM1 are significantly lower in particles produced in HERC6-R10G expressing cells. More importantly, proteins related to the GO biological processes of viral transcription and viral gene expression are significantly under-represented in these virions compared to those produced in cells expressing wildtype HERC6 (Figure 3.4D). Viral membrane composition is important for HIV-1 infectivity. For example, ICAM-1 incorporation into the viral envelope promotes viral attachment through the interaction with LFA-1 on the membrane of CD4+ T cells⁴⁸. Since the cellular adhesion molecule CADM1 was under-represented in the HERC6-R10G samples, we performed a neutralization assay to determine if antibody neutralization of CADM1 on the surface of virions would reduce particle infectivity. Unfortunately, the CADM1 neutralizing antibody did not perform better than the isotype control in our assay, although previous studies have found that the 9D2 IgY mAb against CADM1 inhibited the binding of mast cells to human airway smooth muscle cells⁴⁴ and sensory neurons⁴⁹. Conversely, binding of CADM1 to the extracellular matrix of human airway smooth muscle cells was affected by expression levels of CADM1 and not by antibody binding⁴². It is possible that a similar mechanism might be affecting the binding mediated by CADM1 of the HIV particles to target cells, whereby the reduced expression of CADM1 on virions will inhibit their binding to target cells but antibody neutralization does not hinder it. Future research is needed to determine if CADM1 is a true HIV adhesion molecule which affects infectivity.

A small subset of people are resistant to HIV infection and from the beginning of the HIV-1 epidemic researchers have searched for host genetic factors which contribute to protection from the disease with the hope of capitalizing on these discoveries to deliver a cure. A meta-analysis of 6315 individuals determined that approximately 25% of the variation in viremia setpoint is due to host genetic variation^{50,51}. Most of this variation is attributed to the contribution of HLA and CCR5 mutations, leaving approximately 5.5% of variance associated with other regions of the genome^{50,51}. Expression of HLA-B*57, B*27, B*58:01, B*51, B*13, and B*81:01 are amongst the most protective correlates while, HLA-B*58:02 and HLA-B*35Px alleles are associated with more rapid disease progression⁵⁰. CCR5, specifically the CCR5 Δ 32, is the only genetic variant which has been proven to definitively protect from HIV infection⁵²⁻⁵⁵. So far, three separate patients have been cured of HIV by receiving a bone marrow or stem cell transplant from individuals with the CCR5 Δ 32 mutation and have remained HIV-free without the aid of antiretroviral therapies (ART) for more than 10 years⁵². In two other cases, the HIV positive recipients of a bone marrow transplant (not containing the CCR5 Δ 32 mutation) rebounded approximately 32 weeks after the cessation of ART⁵⁴. These results highlight the power of genetic variation on controlling HIV-1 disease progression.

Other immune sensing molecules such as Toll Like Receptors (TLR's) and restriction factor SNPs have also been shown to influence disease progression. For example, a SNP on TLR4 (D299G) is associated with higher HIV-1 infection⁵⁶⁻⁵⁸ while on TLR3, P554S and L412F are thought to be a protective alleles⁵⁹. TLR7 Q11L, TLR9 G1174A and G1635A are associated with accelerated HIV-1 disease progression⁶⁰⁻⁶². APOBEC3G houses a protective SNP (rs35228531) which reduced the risk of HIV infection for carriers of the minor allele T⁶³. In elite controllers, variation in TRIM5 α (rs10838525) may contribute to viral suppression while rapid progression was found in those harboring a mutation in cyclophilin A (rs6850)⁶⁴. Additionally, 136Q polymorphism of TRIM5 α along with the -2GG genotype was associated with faster disease progression (The Effect of Trim5 Polymorphisms on the Clinical Course of HIV-1 Infection). In tetherin (BST-2) several SNPs (rs3217318, rs10415893, rs145303329, rs12609479) have been reported to

interfere with the expression and function of the potent antiviral molecule^{65,66}. On the other hand HIV-1 infected individuals who possess the BST-2 rs12609479-GG/rs113189798-AG alleles have higher T-cell counts and this mutation is enriched in HIV-1 elite controllers⁶⁷ and the rs9576CA allele is associated with higher CD4 counts and lower viral loads⁶⁸.

With the data obtained in this chapter, we speculate that HERC6-R10G SNP affects the proteins packaged into the viral particles and released from cells in the form of extracellular vesicles. Specifically, proteins involved in the biological processes of viral transcription and gene expression are significantly reduced in these virions, and while these processes are not affected in the producer cells, they seem to have a deleterious effect in the establishment of infection in the target cells. Several proteins have been previously identified as influencing the infectivity of viral particles based on their incorporation into the virion^{48,69}. Incorporation of host protein into viral particles can occur actively, through direct interactions with viral proteins such as the incorporation of LEDGF through its interaction with the integrase portion of Gag-Pol⁷⁰, or Heat shock protein (Hsp) 70 through its interactions with Gag⁷¹; or passively, due to their proximity to the plasma membrane such as tetraspanins⁶⁹. Omitting these proteins from the viral particle often leads to defective virions and abortive infections^{48,69}.

Similar to ICAM-1, integrin $\alpha 4\beta 7$ is incorporated into the viral envelope to facilitate viral homing to the gut and preclusion of these attachment molecules reduces the infectivity of viral particles⁷². On the other hand, incorporation of host SERINC3 and SERINC5 reduces the infectivity of viral particles, although they are counteracted by HIV-1 Nef^{73,74}. The packaging of viral proteins into extracellular vesicles can also have an effect on the infectivity of the viral particles. For example, packaging of Nef into exosomes suppresses the immune response of neighboring cells and makes them more permissive to infection⁷⁵. Liu et al⁷⁶ found that virions produced in cells over-expressing PSGL-1 were significantly less infectious. PSGL-1 is a lymphocyte and myeloid cell specific factor which is induced by IFN γ during HIV-1 infection of primary CD4+ T cells. This study

did not elucidate the exact mechanism by which PSGL-1 reduces particle infectivity, but it illustrates that cellular factors can impact the infectivity of the produced virions in unknown and unexpected ways.

Our study had several limitations. We were only able to repeat the mass spec experiment with one replicate and due to the nature of the isolation technique used we were not able to separate exosomes secreted by the cells from the viral particles. However, our results are consistent with other studies which examined HIV-1 particle composition^{77,78}. Consistently, we identified heat shock proteins (e.g. HSP70, HSP90, and HSP27), actin and actin binding proteins (e.g., ACTN1, moesin, and ezrin) and surface proteins such as HLA-A which have been previously described to be actively incorporated into viral particles⁶⁹. These studies utilized different cell lines (e.g., Sup-T1, THP-1, CEM, and H9) in their experiments so some cell type-specific variation can be expected, however, the overall results are similar. While not conclusive, our results provide the basis for future studies to build on and better elucidate the relationship between the HERC6-R10G SNP, the infectivity of viral particle and consequences on disease progression in a larger cohort.

Our finding that the R10G allele is over-represented in individuals categorized as slow progressors in conjunction with decreased infectivity for virions formed in cells expressing HERC6-R10G suggest that this SNP has a significant role in innate resistance to HIV-1 infection. Although further studies are needed to better understand the mechanism by which this restriction occurs, here, we outline the discovery and initial experiments used to determine the contribution of the R10G SNP to the antiviral activity of HERC6. Further understanding of the multitude of ways the HIV virus interacts with the host restriction factors will pave the way for the discovery of novel antiviral therapeutics to aid in the treatment and/or prevention of AIDS.

3.4 Materials and Methods

3.4.1 Cell Lines

293T cells were obtained from American Type Culture Collection. TZM-bl cells were obtained from NIH AIDS Research and Reference Reagent Program, Division of AIDS, NIAID. Cells were maintained in standard growth medium (Dulbecco's Modified Eagle's Medium (DMEM)), supplemented with 10% heat-inactivated Fetal Bovine Serum (FBS), 100 U/ml Penicillin and 100 µg/ml Streptomycin) at 37°C with 5% CO₂.

3.4.2 Plasmids, transfections, antibodies, and Western blotting

Plasmids: The promoterless empty vector plasmid pGL3, p3xFLAG-CMV10 and pEGFP were obtained from Promega, Sigma and Clontech respectively. Coding regions of HERC5 and HERC6 were obtained from the following sources: HERC6 (NM_017912.3), and HERC5 (NP_057407.2). Details pertaining to the construction of plasmids encoding the various flag-tagged HERC5, and HERC6 constructs can be found in the methods section of Chapter 2 and Table 3. All constructs were verified by sequencing.

Transfections were performed using Lipofectamine 2000 (Invitrogen) per manufacturer's instructions unless otherwise stated. Co-transfections of HERC plasmids with pR9 were performed at a ratio of 10:1 respectively, unless otherwise noted. Standard Western blot analyses were performed as previously described³⁴. Densitometric analysis was performed using ImageJ 1.43u 64-bit version software (NIH, USA).

To generate pH6:R10A, pH6:E67A, pH6:R10A/E67A, and pR10G site-directed mutagenesis was performed on pHERC6 using the primers in Table 4 rows 1 to 4.

Antibodies: The following reagents were obtained through the NIH AIDS Research and Reference Reagent Program, Division of AIDS, NIAID, NIH: HIV-1 p24 Monoclonal Antibody (183-H12-5C) from Dr. Bruce Chesebro and Kathy Wehrly. Anti-FLAG was purchased from Sigma, anti-myc and anti-GAPDH was purchased from Rockland, and anti-eGFP was purchased from Clontech. anti-GAPDH (clone 6C5) was purchased from

EMD/Millipore. CADM1 (9D2) was obtained from MBL International and Chicken IgG Isotype Control was obtained from Novus Biologicals.

3.4.3 Quantitative real-time PCR

The total RNA was extracted using the PureLink RNA mini kit (Ambion, Life Technologies). Using the M-MLV reverse transcriptase and Oligo(dT) primers (Eurofins), 500 ng of RNA was reverse transcribed to cDNA. Prior to qPCR, cDNA samples were diluted 1:5 with water. Each PCR reaction consisted of 10 μ L of SYBR Green Master Mix, 1.6 μ L of gene-specific primers (0.8 μ L of 10 μ M forward primer and 0.8 μ L of 10 μ M reverse primer), 4 μ L of diluted cDNA, and water to a total volume of 20 μ L. Quantification of endogenous mRNA was run on the QuantStudio5 qPCR machine (Applied Biosystems) under the following cycling conditions: 2 min at 95°C and 40 cycles of 5 sec at 95°C, 10 s at 60°C, and 20 s at 72°C. The QuantStudio Design and Analysis Desktop Software (version 1.4) was used to determine the CT for each PCR reaction. Gene-specific forward and reverse primer sets are described in Table 4 rows 5 to 7.

3.4.4 Isolation of PCR fragments containing HERC6 SNP rs111670008 from patients

Genomic DNA was isolated from frozen PBMCs from HIV-1 positive patients within the Ugandan cohort using the QIAGEN QIAamp DNA Blood Mini Kit per the manufacturers protocol. Genomic regions flanking the HERC6 SNP rs111670008 were PCR amplified using the primers in Table 4 row 8. Sequencing was performed at the London Regional Genomics Centre (Robarts Research Institute, Western University).

3.4.5 Ethics Statement

Details pertaining to the Uganda study population have been reported previously [46–50]. Briefly, women who became HIV infected while participating in the Hormonal Contraception and Risk of HIV Acquisition Study in Uganda were enrolled upon primary infection with HIV-1 into a subsequent study, the Hormonal Contraception and HIV-1 Genital Shedding and Disease Progression among Women with Primary HIV Infection (GS) Study. Ethical approval was obtained from the Institutional Review boards (IRBs) from the Joint Clinical Research Centre and UNST in Uganda, from University of Zimbabwe, from the University Hospitals of Cleveland, and recently, from Western University. All adult subjects provided written informed consent and no child participants were included in the study. Protocol numbers and documentation of these approvals/renewals are available upon request. Blood and cervical samples were collected every month for the first six months, then every three months for the first two years, and then every six months up to 9.5 years. Women who had CD4 lymphocyte counts of 200 cells/ml and/or who developed severe symptoms of HIV infection (WHO clinical stage IV or advanced stage III disease) were offered combination ART (cART) and trimethoprim-sulfamethoxazole (for prophylaxis against bacterial infections and *Pneumocystis jirovecii* pneumonia). HIV-1 (subtype A or D) positive patients were stratified into three groups based on their rate of disease progression. Rapid Progressors were characterized by a CD4+ T-cell count < 250 cells/ μ L within the first 3 years post infection (1095 days). Normal Progressors were characterized by a CD4+ T-cell count between 250 cells/ μ L and 499 cells/ μ L 5 years post infection (1825 days) without antiretroviral treatment. Slow progressors were characterized by a CD4+ T-cell count >500 cells/ μ L 5 years post infection (1825 days) without antiretroviral treatment.

3.4.6 Analyses of Sequences, Synteny and Positive Selection

The MEGA 7.0 package was used for the phylogenetic analysis⁸⁰. The amino-terminal end of the small HERCs varies in length among the different members and was not

included for phylogenetic analysis. The first 23 amino acids from HERC5 and HERC6. Modeling of HERC5 and HERC6 RLD was performed with VMD version 1.9.2⁸¹

3.4.7 Mass Spectrometry Sample preparation and Data analysis

Mock (no virus just empty vector control plasmid), Control (empty vector control and R9), HERC6 (HERC6 and R9), HERC6-R10G (HERC6-R10G and R9) virus samples were created in HEK 293T. The virus was concentrated using 100 KDa MWCO centrifuge tubes (Amicon, USA) and washed several times using PBS. Fresh urea lysis buffer (8M Urea, 2% SDS, 10mM DTT, 50mM Ammonium Bicarbonate) was used to lyse the samples. Protein concentration was measured with Pierce 660nm Protein Assay and 100 ug of starting material was used. The samples were reduced and alkylated using 10mM DTT and 100 mM (final concentration) Iodoacetamide solution. Methanol-Chloroform precipitation method was used to clean up the protein samples (see ⁸²). Proteins were resuspended in 100 ul of 50 mM Ammonium Bicarbonate solution and digested with Trypsin/LysC (Promega) and LysC (Wako) enzymes at a ratio of 100:1 sample to enzyme. Samples were incubated overnight at 37°C. Samples were filtered in a Microcon-10kDa centrifugal filter unit with ultracel-10 membrane (Millipore). Samples were analyzed on a Thermo Scientific Q Exactive Plus Orbitrap LC-MS/MS System. Raw files were searched against the human Uniprot databased (20, 274 entries) using the de novo search engine PEAKS® (version 8). Parent and fragment mass error tolerances were set to 20 ppm and 0.05 Da, respectively. Maximum missed cleavages were set to 3 and 1 non-specific cleavage was allowed. Carbamidomethylation was set as a fixed modification, and deamidation, oxidation and acetylation (protein N-term) were included as variable modifications with a maximum of 3 PTMs per peptide allowed. To correct for the sample loading and technical variability, peak areas for each peptide were normalized to the total ion current (TIC). Normalized peak areas of 0 were assumed to be missing not at random and imputed with the lowest ratio detected for the given peptide. Figures were generated using R version 4.1.2 (2021-11-01) with Bioconductor⁸³ packages tidyverse⁸⁴, pheatmap⁸⁵, EnhancedVolcano⁸⁶ and annotated with human genome database

org.Hs.eg.db⁸⁷. Gene ontology analysis was performed with ShinyGo 0.76.3 with the setting of FDR cutoff 0.05⁸⁸.

3.4.8 CADM1 Neutralization Assay

Methods were adapted from Sarzotti-Kelsoe et al., 2014⁸⁹. Briefly, R9 or NL4-3 infectious virus was incubated with either CADM1, VRC01, or isotype control neutralizing antibodies at increasing concentration of 0.014, 0.12, 0.36, 1.1, 3.3, 10, or 30 ug of antibody and 30ug/ml of DEAE dextran for 1 hour at 37°C. 10000 TZM-bl cells were added to the virus-antibody mixture and were incubated for 48 hours at 37 °C. Britelite plus Reporter Gene Assay System (PerkinElmer) was used to detect luciferase activity as per manufacturer's instructions.

3.4.9 Statistical analyses

GraphPad Prism v8 was used for all statistical analyses stated in the text. P values and statistical tests used are stated in the text where appropriate. P values less than 0.05 were deemed significant.

Chapter 4

4 Interferon-Induced HERC5 Inhibits Ebola Virus Particle Production and Is Antagonized by Ebola Glycoprotein

Survival following Ebola virus (EBOV) infection correlates with the ability to mount an early and robust interferon (IFN) response. The host IFN-induced proteins that contribute to controlling EBOV replication are not fully known. Among the top genes with the strongest early increases in expression after infection *in vivo* is IFN-induced HERC5. Using a transcription- and replication-competent VLP system, we showed that HERC5 inhibits EBOV virus-like particle (VLP) replication by depleting EBOV mRNAs. The HERC5 RCC1-like domain was necessary and sufficient for this inhibition and did not require zinc finger antiviral protein (ZAP). Moreover, we showed that EBOV (Zaire) glycoprotein (GP) but not Marburg virus GP antagonized HERC5 early during infection. Our data identify a novel ‘protagonist–antagonistic’ relationship between HERC5 and GP in the early stages of EBOV infection that could be exploited for the development of novel antiviral therapeutics. This chapter was published in *Cells* on September 13, 2021 (see Appendix 1 for publication permissions).

4.1 Introduction

Ebola virus (EBOV) is a member of the Filoviridae family of single-stranded negative-sense RNA viruses with a filamentous morphology. EBOV infection results in severe hemorrhagic fever and can lead to death 6-16 days after the onset of symptoms in up to 90% of cases, making EBOV one of the most virulent pathogens to infect humans¹. Studies involving primate models, and human studies carried out during the 2013–2016 outbreak, showed that EBOV exposure results in an early and robust immune response, largely characterized by the up-regulation of IFN-stimulated genes^{2–12}. A contributing factor to the pathophysiology of EBOV infection is the ability of the virus to evade the host IFN response^{7,13–16}. Using *in vitro* models of infection, it was shown that EBOV is able to evade the innate immune response through various IFN antagonisms, notably involving VP24 and VP35 proteins^{17–19}. The key mediators of this early cellular IFN

response to EBOV and how EBOV withstands this early response are not fully characterized. Restriction factors are key intrinsic mediators of the early IFN response and potentially inhibit different steps in the life cycle of evolutionarily diverse viruses in the absence of viral antagonists²⁰. Bone marrow stromal cell antigen 2 (BST-2)/tetherin is one such factor that potentially inhibits the release of EBOV from cells by tethering virions to the surface of cells^{21,22}. This inhibition is counteracted by EBOV GP^{23–26}. IFN-inducible trans-membrane proteins 1–3 (IFITM1–3) comprise another family of factors that restrict the cellular entry of EBOV, although an EBOV antagonist to these proteins has yet to be identified^{27,28}. HECT and RCC1-like containing domain 5 (HERC5) are some of the genes with the strongest early increases in expression in multiple tissues after EBOV infection^{3,5,6,29}. HERC5 is an evolutionarily ancient restriction factor that inhibits the replication of diverse viruses^{30–36}. By virtue of its C-terminal HECT domain, HERC5 is the main cellular E3 ligase for conjugating ISG15 to substrates and localizes to polyribosomes to modify newly translated viral proteins, thereby disrupting key aspects of viral particle production^{30,37–39}. E3 ligase-independent antiviral activity has also been demonstrated towards HIV-1, where it inhibits the nuclear export of incompletely spliced viral RNAs by a mechanism requiring its N-terminal RCC1-like domain (RLD)³⁰. Here, we examined the antiviral activity of HERC5 towards EBOV VLP production and replication. We identified a novel E3 ligase-independent mechanism by which HERC5 inhibits viral particle production involving the depletion of EBOV mRNAs. In addition, we demonstrated that EBOV GP antagonizes HERC5 activity and rescues EBOV production and replication.

4.2 Results

4.2.1 HERC5 Inhibits EBOV trVLP Replication

Previous studies have identified HERC5 as a potent inhibitor of diverse viruses^{30,31,32,33,34,35,36}. To determine if HERC5 restricts EBOV particle production and replication, we used an EBOV (Zaire) transcription- and replication-competent VLP (trVLP) system. This system utilizes a tetracistronic minigenome ('4cis') carrying a

luciferase reporter gene together with VP40, VP24, and GP (Figure 4.1A)^{40,41}. The advantage of this system over conventional VLP assays is that the viral proteins VP40, GP and VP24 are encoded by the minigenome and expressed from the EBOV promoter in a more natively regulated fashion⁴⁰. The co-expression of this minigenome with NP, VP35, VP30, and L drive genome replication and transcription, synthesis of the minigenome-encoded proteins, and formation of infectious trVLPs. These trVLPs incorporate minigenomes and are capable of undergoing multiple rounds of replication and infection in target cells that express NP, VP35, VP30, L and Tim-1 (Figure 4.1B). The replication of these trVLPs was quantified over multiple passages (every three days) by measuring the luciferase reporter activity within cells. As a negative control, the plasmid carrying the Ebola L gene was omitted from the transfections, which abrogated the trVLP formation. Compared to the control cells transfected with an empty vector plasmid, cells expressing HERC5 exhibited a significant reduction in trVLP replication over four passages (Figure 4.1C). The reduction in luciferase reporter activity also correlated with a reduction in GP and VP40 mRNA levels (Figure 4.1D).

Figure 4.1 HERC5 inhibits EBOV trVLP replication. HERC5 Inhibits EBOV VP40 Particle Production

A) Schematic depicting EBOV full-length genome and the derived tetracistronic minigenome. **(B)** The trVLP propagation assay. A tetracistronic EBOV minigenome (4cis) is expressed in cells together with the viral ribonucleoprotein complex (RNP) proteins (NP, VP35, VP30 and L). After the initial transcription by a co-expressed T7

polymerase, the minigenome is replicated and transcribed by the RNP proteins. Expression of VP40, GP and VP24 from the minigenome leads to the formation of infectious trVLPs containing minigenomes, which can infect target cells. Multiple infectious cycles can be modeled in cells expressing NP, VP35, L, VP30 and Tim-1 without the need for additional transfections of plasmids carrying VP40, GP and VP24. The figure was adapted from⁴⁰, copyright © American Society for Microbiology, J. Virol. 88, 2014, 10,511–10,524, doi:10.1128/JVI.01272-14. **(C)** Quantification of trVLP propagation in the presence and absence of HERC5. The trVLP propagation assay was performed using tetracistronic minigenomes carrying a luciferase reporter, EBOV VP40, VP24 and EBOV GP over four passages (spanning 12 days). All EBOV minigenomes and plasmids carrying the EBOV proteins are based on EBOV H. sapiens-tc/COD/1976/Yambuku-Mayinga. Luciferase reporter activity relative to the control (trVLPs propagated in the absence of HERC5) is shown. The data shown represent the average (\pm S.E.M.) of four independent experiments. Linear regression analysis, $F = 39.14$. $DF_n = 1$, $DF_d = 36$; $p < 0.0001$. **(D)** The mRNA of GP and VP40 was measured using qRT-PCR at each passage. The data shown represent the average (\pm S.E.M.) of the four independent experiments represented in part C. * $p < 0.05$; One-way ANOVA with Dunnet's multiple comparisons test compared to the control.

Previous studies showed that HERC5 interferes with the function of key viral structural proteins^{30,31,36,37}. The EBOV structural protein VP40 is necessary and sufficient for the assembly and budding of virus particles. When expressed in the absence of any other viral protein, VP40 can form VLPs that bud and are released from cells similar to wild-type EBOV⁴²⁻⁴⁴. To determine if HERC5 targets VP40, we co-transfected 293T cells with a plasmid carrying VP40 and increasing concentrations of plasmids carrying either empty vector control or FLAG-tagged HERC5. VP40 protein levels within cells and in VLPs were measured using quantitative Western blotting. HERC5 transfection did not alter cell viability (Appendix 3). As shown in Figure 4.2A and Appendix 3B, C, HERC5 inhibited

the production of VP40 VLPs in a dose-dependent manner when VP40 is tagged with either GFP or with FLAG but had no effect on intracellular GFP levels. As a control, transfection with HERC4, a closely related member of the small HERC family, did not significantly alter cell viability, VP40 or GFP levels (Appendix 3D–F). In contrast, when HERC5 mRNA levels were reduced using RNA interference, an increase in intracellular VP40 protein levels and an increase in the production of VP40 VLPs were observed compared to the control cells (Figure 4.2B, C).

We also assessed the impact of HERC5 expression on VLPs using confocal microscopy and transmission electron microscopy (TEM). As expected, cells expressing VP40 with enhanced green fluorescent protein fused at its amino-terminus (VP40-EGFP) exhibited punctate fluorescence at the cell surface (Figure 4.2D). In contrast, cells co-expressing VP40-EGFP and HERC5 exhibited substantially less punctate fluorescence at the cell surface compared to the control cells. The presence of VP40 protein at the cell surface was also confirmed using TEM and immunogold TEM (Figure 4.2E, F). In cells expressing VP40-EGFP alone, an accumulation of immunogold particles was observed in budding structures at the cell surface, which was significantly different from a random distribution (Appendix 5 and Appendix 6). Cells expressing HERC5 exhibited markedly fewer VP40-EGFP-containing structures at the cell surface compared to the control cells. In addition, cells expressing HERC5 exhibited on average eight-fold fewer immunogold particles per cell compared to the control cells (Figure 4.2G). Notably, the few VP40-EGFP-containing structures that were observed in cells expressing HERC5 were located predominantly in a region under the plasma membrane.

We then asked whether the reduced VP40 protein levels correlated with reduced intracellular VP40 mRNA levels. The quantitative PCR showed that 293T cells co-expressing HERC5 and FLAG-tagged VP40 exhibited reduced intracellular levels of VP40 mRNA (nine-fold) compared to the control cells not expressing HERC5 (Figure 4.2H). Similar results were obtained when HERC5 was co-expressed with a VP40-EGFP fusion protein (Appendix 4). As a control, HERC5 expression had no significant effect on

EGFP mRNA levels when EGFP was expressed alone (Figure 4.2H and Appendix 4). To determine if the effect of HERC5 is specific for VP40 mRNA, we assessed the impact of HERC5 expression on the level of other EBOV mRNAs. Cells co-expressing HERC5 and either VP30, VP35, L or NP exhibited a two- to five-fold reduction in mRNA levels compared to the control cells (Figure 4.2H). Together, these data show that HERC5 inhibits EBOV VP40 particle production by a mechanism involving the depletion of EBOV mRNAs.

Figure 4.2 HERC5 inhibits EBOV VP40 particle production.

(A) 293T cells were co-transfected with plasmids carrying FLAG-tagged VP40 (pFLAG-VP40) and increasing concentrations of FLAG-tagged HERC5 (pFLAG-HERC5). Empty vector plasmid was transfected in the condition with no HERC5 and used to ensure equal amounts of DNA were transfected in each condition. Forty-eight hours post-transfection, purified VLPs released into the cell supernatant and intracellular protein were subjected to quantitative Western blot analysis using anti-FLAG, anti-VP40 and anti-GAPDH. The average densitometric quantification of VP40 protein bands is shown to the right after normalization to GAPDH levels (\pm S.E.M.). A representative Western blot of four independent experiments is shown. **(B)** 293T cells were co-transfected with pFLAG-VP40 and either scrambled short-hairpin RNA (shRNA) (scram) or HERC5shRNA (shHERC5). Forty-eight hours after transfection, intracellular levels of HERC5 mRNA were quantified via qPCR. Data shown is the average (\pm S.E.M.) of three independent experiments. **(C)** 293T cells were transfected with either scrambled short-hairpin RNA (shRNA) (scram) or HERC5shRNA (shHERC5) for 24 h and then with pFLAG-HERC5 and pFLAG-VP40 for forty-eight hours. Purified VLPs released into the cell supernatant and intracellular protein were subjected to quantitative Western blot analysis using anti-FLAG and anti-GAPDH. The average densitometric quantification of VP40 protein bands is shown to the right after normalization to GAPDH levels (\pm S.E.M.). A representative Western blot of four independent experiments is shown. **(D)** HeLa cells were co-transfected with pVP40-EGFP and either empty vector (control) or pFLAG-HERC5 and visualized using confocal microscopy 48 h post-transfection. **(E)** 293T cells were “mock” transfected (control), transfected with empty vector and pVP40-EGFP, or transfected with pFLAG-HERC5 and pVP40-EGFP and analyzed via transmission electron microscopy (TEM) after 48 h. Virus particles beneath the plasma membrane are indicated with arrows. **(F)** Representative immunogold TEM images of 293T cells transfected as in **(E)** and labelled with 5 (\pm 2) nm anti-GFP immunogold particles. Immunogold-labelled VLPs are indicated with arrows. Scale bars = 500 nm. **(G)** The number of gold particles per positive cell was counted and presented as the average

number of particles per cell (+/- S.E.M). **(H)** 293T cells were co-transfected with plasmids carrying FLAG-HERC5 (or empty vector) and either EBOV VP40, VP30, VP35, L, NP, GP or GFP at a ratio of 10:1 (HERC5: EBOV plasmids). Forty-eight hours post-transfection viral mRNA was measured using qPCR after normalization to GAPDH mRNA levels. Data shown are representative of three independent experiments (+/- S.E.M.). **** p < 0.0001, *** p < 0.001, ** p < 0.01, * p < 0.05; One-way ANOVA with Dunnet's multiple comparisons test compared to the control (A, G); Student's paired t-test (B, C, H).

4.2.2 HERC5 RLD Is Necessary and Sufficient for Inhibition of VP40 Particle Production

To determine if the RLD or HECT domains of HERC5 are required for inhibition, we tested the ability of several HERC5 mutants to inhibit VP40 particle production. 293T cells were co-transfected with plasmids carrying VP40 and either empty vector (control), wild type HERC5 or HERC5 mutants lacking the RCC1-like domain (HERC5- Δ RLD), spacer region (HERC5- Δ spacer) or HECT domain (HERC5- Δ HECT). We also tested the HERC5 RLD alone (HERC5-RLDonly) or HERC5 containing a cysteine to an alanine point mutation of residue 994 (HERC5-C994A), which specifically inactivates its E3 ligase activity (4.3A). Each of the FLAG-tagged mutant proteins was expressed at similar levels in 293T cells (Figure 4.3B).

As shown in Figure 4.3C, cells expressing wild type HERC5, HERC5- Δ HECT or HERC5-C994A reduced VP40 protein levels, which also correlated with reduced VP40 VLP production. In contrast, cells expressing HERC5- Δ RLD, and to a lesser extent HERC5- Δ spacer, exhibited a diminished capacity to reduce VP40 protein levels and VP40 VLP production. Notably, expression of the HERC5 RLD alone (HERC5-RLDonly) reduced VP40 protein levels and VP40 VLP production similar to wild-type HERC5 (Figure 4.3D). We also examined the ability of the different HERC5 mutants to reduce VP40 mRNA levels. All HERC5 mutants except for HERC5- Δ RLD significantly reduced VP40 mRNA levels (4.3E). Taken together, these data show that the HERC5

RLD is necessary and sufficient to reduce VP40 mRNA levels and VP40 particle production.

Figure 4.3 The RLD is necessary and sufficient for HERC5-mediated restriction.

(A) Schematic of the different HERC5 mutant constructs. **(B)** Representative Western blot showing consistent expression of wild-type HERC5 and mutant forms of HERC5. 293T cells were transfected with either empty vector or plasmids carrying FLAG-tagged HERC5, HERC5- Δ RLD, HERC5-RLDonly, HERC5- Δ Spacer, HERC5- Δ HECT or HERC5-C994A. Forty-eight hours after transfection, cell lysate was subjected to Western blot analysis using anti-FLAG and anti-GAPDH. **(C)** 293T cells were co-transfected with plasmids carrying FLAG-tagged VP40 and either empty vector, wild-type HERC5 or one of the HERC5 mutants listed in (A). Forty-eight hours post-transfection, purified VLPs released into the supernatant and intracellular protein were examined by Western blotting using anti-FLAG and anti-GAPDH. VP40 protein levels were quantified densitometrically after normalization to GAPDH levels (graphs on the right). **(D)** 293T cells were co-transfected with plasmids carrying VP40-EGFP and either empty vector, HERC5 or HERC5-RLDonly. Cell lysates and VLPs were analyzed via Western blotting using anti-GFP and anti-GAPDH. VP40-EGFP protein levels were quantified densitometrically (graphs on the right). **(E)** 293T cells were co-transfected with plasmids carrying FLAG-tagged VP40 and either empty vector, HERC5, HERC5- Δ RLD, HERC5-RLDonly, HERC5- Δ Spacer, HERC5- Δ HECT or HERC5-C994A. Forty-eight hours post-transfection, mRNA was isolated and used to measure intracellular VP40 mRNA levels using qPCR. All data shown are representative of three independent experiments (\pm S.E.M.). **** $p < 0.0001$, *** $p < 0.001$, ** $p < 0.01$, * $p \leq 0.05$, ns (not significant) $p > 0.05$; One-way ANOVA with Dunnet's multiple comparisons test compared to the control.

4.2.3 HERC5 Depletes VP40 mRNA Independently of ZAP

ZAP (also called Zinc finger CCCH-type, antiviral 1, ZC3HAV1, and Poly (ADP-ribose) polymerase 13, PARP13) is an antiviral protein that causes significant loss of viral mRNAs from evolutionarily diverse RNA viruses, including Filoviridae, Retroviridae, Togaviridae and Hepadnaviridae⁴⁵⁻⁵¹. We, therefore, asked if ZAP was required for

HERC5-mediated depletion of EBOV mRNA. We co-expressed VP40 and HERC5 in 293T cells that were knocked out for all ZAP isoforms and measured VP40 mRNA and protein levels using qPCR and Western blotting^{52,53}. Cells expressing HERC5 in the absence of ZAP significantly reduced VP40 mRNA levels (Figure 4.4A). Exogenous expression of ZAP (short isoform) in the ZAP knockout cells reduced VP40 mRNA levels as previously shown^{48,52}. Co-expression of HERC5 and ZAP together resulted in an enhanced loss of VP40 mRNA (Figure 4.4A). In support of this observation, cells expressing HERC5 in the absence of ZAP significantly reduced intracellular VP40 protein and VP40 VLPs the cell supernatant (Figure 4.4B, C). Together, these data show that ZAP is not required for HERC5-mediated reduction of VP40 mRNA.

Figure 4.4 HERC5 restricts VP40 independently of ZAP.

293T ZAP knockout cells were co-transfected with plasmids carrying FLAG-tagged VP40 and either empty vector control, HERC5, ZAP (short isoform), or HERC5 and ZAP (short isoform). Twenty-four hours post-transfection, cell lysates and VLP-containing supernatants were harvested. (A) Intracellular VP40 mRNA levels were measured using

qPCR and normalized to GAPDH. The data shown is representative of four independent experiments. **(B)** Purified VLPs released into the cell supernatant and intracellular proteins were subjected to Western blot analysis using anti-FLAG and anti-GAPDH. Representative Western blot of three independent experiments is shown. **(C)** The average densitometric quantification of VP40 protein bands from B is shown after normalization to GAPDH levels. Results are presented as mean (\pm SEM) fold changes in VP40 protein or mRNA. **** $p < 0.001$, *** $p < 0.001$, One-way ANOVA with Tukey's multiple comparisons test.

4.2.4 EBOV GP and L Proteins Antagonize HERC5

Despite an early and robust IFN-signaling response to EBOV infection, EBOV proteins ultimately suppress this response leading to pathogenesis²⁻¹². Given the potent antiviral activity of HERC5 towards EBOV mRNAs, we asked if any of the EBOV proteins could antagonize this activity. VP40 mRNA levels in cells co-expressing HERC5 and various EBOV proteins were measured by qPCR. As shown in Figure 4.5A, VP40 mRNA levels were rescued in cells co-expressing GP or L protein, but not VP30, VP35, NP or the non-EBOV protein vesicular stomatitis virus-G (VSV-G) protein. Western blot analysis of cell lysates correlated with the qPCR data where only L and GP proteins rescued intracellular VP40 protein levels (Figure 4.5B). Western blot analysis of VP40 VLPs in the supernatant revealed that GP but not L protein rescued VLP production, indicating that only GP was able to fully rescue VLP production.

To determine if the ability of EBOV GP to antagonize HERC5 is specific to the Ebolavirus genus, we tested the ability of Marburg virus (MARV) GP, which belongs to the Marburgvirus genus, to antagonize HERC5. In contrast with EBOV GP, co-expression of MARV GP failed to rescue VP40 VLP production (Figure 4.5C). Together these data show that EBOV GP antagonizes HERC5 activity, and that this antagonism does not appear to be conserved between filovirus genera.

Figure 4.5 EBOV GP and L antagonize HERC5.

293T cells were co-transfected with plasmids carrying FLAG-tagged VP40 and either empty vector or HERC5 and one plasmid carrying either EBOV VP30, VP35, L NP, GP, or VSV-G. Forty-eight hours post-transfection, VP40 mRNA was measured using qPCR (**A**) and VP40 protein levels in cell lysates and VLPs released into supernatant were analyzed by quantitative Western blotting and quantified densitometrically after normalization to GAPDH levels (**B**). (**C**) 293T cells were co-transfected with plasmids carrying FLAG-tagged VP40 and either empty vector or HERC5, and one of EBOV GP (eGP) or MARV GP (mGP). Forty-eight hours post-transfection, VP40 protein levels in cell lysates and VLPs released into the supernatant were analyzed via Western blotting using anti-FLAG and anti-GAPDH. The data shown represent the average (\pm S.E.M.) of three independent experiments. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, **** $p < 0.0001$, ns (not significant) $p > 0.05$; One-way ANOVA with Dunnett's multiple comparisons test compared to the control (A); Student's paired t-test (B, C).

4.2.5 EBOV and MARV GP Differentially Antagonize HERC5 Inhibition of EBOV trVLP Replication

We utilized the EBOV trVLP system described in Figure 4.1 to determine if genus-specific GP (EBOV or MARV) could antagonize the ability of HERC5 to inhibit trVLP replication. To test the effect of different GPs on trVLP replication, two different sets of trVLP particles were generated at P0. One set contained EBOV GP (trVLP EBOV GP) and was generated as described in Figure 4.1A. The second set was generated in an identical way except that the EBOV GP gene in the '4cis' plasmid minigenome was substituted with the MARV GP gene (trVLP MARV GP). This allowed us to test the impact of different GPs in the VLPs while maintaining the same background of EBOV proteins. As a negative control, the plasmid carrying the Ebola L gene was omitted from the transfections, which abrogates trVLP formation. Compared to the control cells not expressing HERC5, cells expressing HERC5 exhibited significantly reduced levels of trVLP MARV GP and trVLP EBOV GP replication over four passages (spanning 12 days) (Figure 4.6). Notably, HERC5 inhibited trVLP MARV GP replication significantly

more than trVLP EBOV GP replication over two passages ($p < 0.01$, Two-way ANOVA). Together, these data show that EBOV GP and MARV GP differentially antagonize HERC5 inhibition of EBOV trVLP replication.

Figure 4.6 EBOV GP and MARV GP differentially antagonize HERC5.

Quantification of trVLP propagation in the presence and absence of HERC5. The trVLP propagation assay was performed using tetracistronic minigenomes carrying a luciferase reporter, EBOV VP40, VP24 and either EBOV GP or MARV GP over four passages (spanning 12 days). All EBOV minigenomes and plasmids carrying the EBOV proteins are based on EBOV H. sapiens-tc/COD/1976/Yambuku-Mayinga. As a negative control ('No L'), the plasmid carrying the Ebola L gene was omitted from the transfections. Luciferase reporter activity relative to the control (trVLPs propagated in the absence of HERC5) is shown. The data shown represent the average (\pm S.E.M.) of at least six independent experiments. **** $p < 0.0001$, * $p \leq 0.05$, ns (not significant) $p > 0.05$; Two-way ANOVA with Dunnett's multiple comparisons test compared to the no HERC5 control.

4.3 Discussion

Hundreds of IFN-induced proteins are part of the early and robust immune response to EBOV infection in primates²⁻¹³. Characterization of the key effector proteins of this

defense and how EBOV overcomes them will provide a better understanding of the virus–host interactions that occur early in infection. HERC5 is one of the most up-regulated antiviral proteins in the early response to EBOV infection *in vivo*; however, its role in EBOV replication was previously unknown^{3,6,8,28}.

In this study, we showed that HERC5 inhibits EBOV VLP replication via a novel E3 ligase-independent mechanism. This mechanism involves the depletion of viral mRNAs and requires the RLD domain of HERC5. We previously showed that HERC5 inhibits the nuclear export of HIV-1 RNA genomes by a different E3 ligase-independent mechanism, one that also requires the RLD domain of HERC5³⁰. These E3 ligase-independent antiviral activities, together with its well-documented E3 ligase-dependent antiviral activities⁵⁴, identifies HERC5 as a multifunctional antiviral protein. It is perhaps not surprising that HERC5 has evolved multiple mechanisms of restriction of viruses. The ancestral HERC gene is believed to have arisen from a gene fusion event between an RCC1-like gene and a HECT gene^{55,56}. This fusion event gave rise to a family of small HERC proteins containing an amino-terminal RLD and a carboxyl-terminal HECT domain that is highly conserved among vertebrates spanning >595 million years of evolution^{55–57}. Moreover, HERC5 has been evolving under strong positive selection, which is characteristic of many host restriction factors involved in an evolutionary struggle with viruses^{30,56,58}. The ability of HERC5 to inhibit viruses via both E3 ligase-dependent and -independent mechanisms would confer a strong evolutionary advantage to its host, making it more difficult for viruses to evolve countermeasures to HERC5.

Like HERC5, ZAP is present in evolutionarily diverse vertebrates and has evolved under strong positive selection^{30,57,59}. ZAP targets diverse viruses such as HIV-1, MoLV and XMRV (Retroviridae), Ebola and Marburg viruses (Filoviridae), alphavirus, Sindbis, Semliki Forest and Ross River viruses (Togaviridae), hepatitis B virus (Hepadnaviridae) and double-stranded DNA murine gamma herpesvirus (Herpesviridae)^{45,47,49,51,53,60–64}. ZAP is known to inhibit a wide range of antiviral activities, including recruiting the exosome complex to target viral RNAs for degradation^{45,47,49,51,53,60–64}. ZAP also exhibits

virus specificity since it has no antiviral effect on vesicular stomatitis, poliovirus, yellow fever, and herpes simplex I viruses⁴⁵. We showed here that HERC5 depletes EBOV mRNAs in a ZAP-independent manner. Our finding that the HERC5 RLD is necessary and sufficient for EBOV mRNA depletion further supports an E3 ligase-independent mechanism of restriction. It was previously shown that the RLD is required for the association of HERC5 with polyribosomes³⁷. It is possible that HERC5 exploits this interaction to recruit other RNA degradation machinery to EBOV mRNAs.

Although we showed that the RLD alone was necessary and sufficient to inhibit particle production, HERC5 lacking the RLD failed to completely inhibit VP40 VLP particle production. Since the RLD is important but not essential for its E3 ligase activity, it is possible that the E3 ligase activity of HERC5 also confers some antiviral activity towards VLP production via ISGylation of viral and/or host proteins involved in particle production^{39,65,66}. It was previously shown that over-expression of ISG15 alone inhibited budding of EBOV VP40 VLPs by disrupting Nedd4 function and subsequent ubiquitination of VP40, which is necessary for viral egress⁶⁷. It is unknown whether HERC5 was involved in this activity since it was not investigated. Although our data show that the predominant mechanism by which HERC5 inhibits EBOV VLP production involves the depletion of EBOV mRNAs, visual inspection of cells co-expressing EBOV VP40 and HERC5 by TEM and confocal microscopy revealed an accumulation of the VP40 protein at the localized regions in the plasma membrane in some cells, consistent with the idea of a second mechanism of inhibition acting later in particle production. HERC5-induced trapping of virus particles at the plasma membrane has also been observed with HIV-1⁶⁵. However, it is also possible that these accumulations represent particles in the process of budding that have escaped HERC5 restriction. HERC5 reduced intracellular mRNA levels of viral protein expressed both from a plasmid system (Figure 4.2H) and of viral mRNA expressed from a tetracistronic minigenome. It is unknown how HERC5 can target viral RNAs but not non-viral RNA such as GFP. Perhaps virus-specific RNA sequences recruit HERC5 and/or RNA depletion machinery similar to how

ZAP selectively recognizes high CpG-containing viral RNA. Further studies are needed to decipher this novel antiviral function of HERC5.

Animal model studies have suggested that the Type I IFN response plays an important role in restricting EBOV replication and that the ability of EBOV to overcome this response may be a requirement for lethal infection^{68,69}. Although EBOV VP24 and VP35 can act broadly to dampen the IFN response, several IFN-induced antiviral proteins, including HERC5, are also highly upregulated early in response to other stimuli associated with infection, such as pro-inflammatory cytokines⁷⁰⁻⁷². As such, it is likely that EBOV evolved additional antagonists of such antiviral proteins. Indeed, EBOV GP can directly antagonize the restriction factor BST-2/tetherin without altering BST-2/tetherin expression levels or cellular localization⁷³⁻⁸⁰. As shown herein, EBOV GP also antagonizes HERC5 without altering HERC5 expression levels. Although controversial, GP sequence diversity has been shown to affect EBOV transmission and virulence, as demonstrated in the 2013-2016 EBOV epidemic^{81,82}. We showed here that variations in GP sequence, such as those found between different filovirus genera (e.g., EBOV and MARV), also influence the potency of antagonism of HERC5 during the early stages of EBOV trVLP replication. It is unclear how GP, which is predominantly localized to the plasma membrane, can rescue EBOV mRNA levels. GP expression is known to alter the expression and trafficking of select cellular proteins; therefore, it is possible that proteins involved in viral RNA stability are affected by GP expression⁸³⁻⁸⁵. Important next steps will be to characterize the mechanism of GP antagonism and to test the importance of this HERC5-GP axis early in infection using animal models.

It is interesting that EBOV L protein was also able to rescue HERC5-induced VP40 mRNA depletion but unable to antagonize the release of VP40 VLPs into the cell supernatant. The mechanism underlying this antagonism is not fully understood; however, it was previously shown that L protein antagonizes ZAP⁴⁸. It is possible that L protein also specifically antagonizes HERC5-induced depletion of mRNAs. However, we speculate that the E3 ligase activity of HERC5 remains functional, leading to the

ISGylation of viral and/or host proteins and subsequent arrest of later steps in viral particle production.

In conclusion, we showed that HERC5 inhibits EBOV virus particle production by a mechanism involving the depletion of EBOV mRNAs. Our data also identifies a novel ‘protagonist–antagonistic’ relationship between HERC5 and GP early in EBOV infection. With the ability to inhibit HERC5 and other restriction factors, GP is an attractive target for the development of small molecule compounds that interfere with this antagonism.

4.4 Materials and Methods

4.4.1 Cell Lines

293T and HeLa cells were obtained from American Type Culture Collection. 293T ZC3HAV1 (ZAP) knockout cells were obtained from Dr. Takaoka (Hokkaido University, Japan) via Dr. Li (University of California, Los Angeles, CA, USA) and Dr. MacDonald (The Rockefeller University, New York, NY, USA). Cells were maintained in standard growth medium (Dulbecco’s Modified Eagle’s Medium (DMEM)), supplemented with 10% heat-inactivated Fetal Bovine Serum (FBS), 100 U/mL Penicillin and 100 µg/mL Streptomycin) at 37 °C with 5% CO₂.

4.4.2 Plasmids, Transfections, Antibodies and Quantitative Western Blotting

Expression plasmids carrying FLAG-tagged HERC5, HERC5- Δ RLD, HERC5- Δ HECT and HERC5-C994A, and HERC4 have been described previously³⁶. The plasmid carrying FLAG-tagged RLD only (pFLAG-RLDonly) was generated by standard restriction enzyme cloning of the HERC5 RLD (containing a 3’ stop codon) into p3xFLAG-CMV-10 (Sigma). The promoterless empty vector plasmid pGL3, pEGFP-C1 (pEGFP) and pZAP (short isoform) were obtained from Promega, Clontech and Dharmacon, respectively. pLKO.1/scrambled shRNA and pLKO.1/HERC5 shRNA were previously described^{30,65}. VP40 and GP were cloned into p3xFLAG-CMV-10 (Sigma) to generate pFLAG-VP40, pFLAG GP and pEGFP-C1 (containing a CMV promoter)

(Clontech) to generate pVP40-EGFP using standard restriction enzyme cloning. EBOV expression plasmids: pCAGGS plasmids (containing a CMV enhancer, chicken beta-actin promoter and beta-actin intron sequence) carrying only EBOV (Zaire) VP40, VP30, VP35, L, NP, or GP were obtained from Dr. Kawaoka (University of Wisconsin)⁸⁶. Plasmids for the trVLP assay were provided by Dr. Hoenen (Friedrich-Loeffler-Institute, Germany): Plasmids carrying NP, VP35, VP30, L, Tim-1, T7 and the tetracistronic minigenomes (p4cisvRNA-hrLuc, p4cis-vRNA-EGFP) have been previously described^{40,87}. All EBOV gene sequences in the minigenomes and plasmids carrying NP, VP35, VP30, and L originated from the Zaire EBOV isolate *H. sapiens*-tc/COD/1976/Yambuku-Mayinga. The EBOV GP and MARV GP expression plasmids were kind gifts of Dr. Cunningham (Brigham and Women's Hospital)^{88,89}. Transfections were performed using Lipofectamine 2000 (Invitrogen) per manufacturer's instructions unless otherwise stated. Co-transfections of HERC5 plasmids with pVP40 were performed at a ratio of 10:1, respectively, unless otherwise noted. VP40 VLPs were purified from cell supernatants by centrifugation over a 20% sucrose cushion at 21,000× *g* for 2 h. Cell lysates and VP40 VLP pellets were subjected to quantitative Western blot analyses using LI-COR, as previously described⁶⁵. Densitometric analysis was performed using ImageJ 1.53e 64-bit version software. Antibodies: Anti-FLAG was purchased from Sigma, anti-ZAP from AbCam (Cat. #ab154680), anti-VP40 from GeneTex (Cat. #GTX134034), anti-MARV GP from Alpha Diagnostic International (Cat. #MVGP12-A), anti-EBOV GP from Bio-Techne (Cat. #MAB9016), anti-β-actin from Rockland, anti-EGFP from Clontech and anti-GAPDH (clone 6C5) from EMD/Millipore.

4.4.3 Confocal Immunofluorescence Microscopy

HeLa cells were cultured in 12-well plates on 18 mm coverslips and co-transfected with either pFLAG-HERC5 and pVP40-EGFP (10:1 ratio) or pGL3 and pVP40-EGFP (10:1 ratio). Twenty-four hours after transfection, the coverslips containing the cells were washed twice with PF buffer (1× PBS + 1% FBS), fixed for 10 min in 1× PBS containing 4% formaldehyde and 2% sucrose, permeabilized in 1× PBS containing 0.1% Triton X 100 (Sigma) and then washed twice more with PF buffer. Coverslips were incubated with

primary antibody rabbit anti-FLAG (1:500 dilution) for 1 h, washed 3× with PF buffer and incubated with either secondary antibody anti-rabbit 594 (1:1000) for 1 h. Coverslips were washed 3×, incubated in Hoechst 33342 (1:10,000 dilution) (Life Technologies) for 5 min and washed 6× with PF buffer. Coverslips were then mounted on glass slides with 10 µL Vectashield mounting media (Vector Laboratories Inc., Burlingame, CA, USA) and sealed with nail polish. Confocal micrographs were obtained using a Leica TCS SP8 (Leica Microsystems) microscope, and Leica Application Software X was used for image acquisition.

4.4.4 Transmission Electron Microscopy

Cells were co-transfected with empty vector or pFLAG-HERC5 and pVP40-EGFP at a 10:1 ratio. After 48 h, cells were resuspended in media, fixed in 2.5% glutaraldehyde in 0.1 M sodium cacodylate (pH 7.4) for 2 h, and washed 3× in 0.1 M sodium cacodylate. Cells were pelleted and fixed with 2% osmium tetroxide in sodium cacodylate. After ~1 h in the dark, cells were washed 3× in ddH₂O. Water was discarded, and samples were left at 4 °C overnight. Samples were dehydrated by adding 1 mL 20% acetone in ddH₂O, mixed and incubated for 10 min at room temperature. Cells were pelleted, acetone removed, and the procedure was repeated with 50%, 70%, 90%, 100%, 100% and 100% acetone. Cells were embedded in resin by adding 1 mL of a 2:1 mix of acetone: resin (Epon) and incubated for ~4 h at room temperature in a rotating tube shaker. Cells were pelleted, acetone: resin mix was discarded and repeated with a 1:1 mix overnight, 1:2 mix overnight, and finally, resin only overnight. Samples were cut in 70 nm slices using a Sorval Ultracut ultramicrotome and placed onto 400 mesh nickel grids (Embra). Grids were placed on drops of 2% uranyl acetate in ddH₂O to stain for 20 min in the dark and washed 5–6× in ddH₂O for 1 min. Samples were then stained in drops of Sato's lead citrate (5 mM calcined lead citrate, 11 mM lead nitrate, 11 mM lead acetate, 95 mM sodium citrate) for 1 min and washed using ddH₂O. Samples were imaged using a Phillips CM10 Transmission Electron Microscope. The AMT Advantage digital imaging system was used for image acquisition.

4.4.5 Quantitative PCR

The total RNA was extracted using the PureLink RNA mini kit (Ambion, Life Technologies). Using the M-MLV reverse transcriptase and Oligo(dT) primers (Eurofins), 500 ng of RNA was reverse transcribed to cDNA. Prior to qPCR, cDNA samples were diluted 1:5 with water. Each PCR reaction consisted of 10 μ L of SYBR Green Master Mix, 1.6 μ L of gene-specific primers (0.8 μ L of 10 μ M forward primer and 0.8 μ L of 10 μ M reverse primer), 4 μ L of diluted cDNA, and water to a total volume of 20 μ L. Quantification of endogenous mRNA was run on the QuantStudio5 qPCR machine (Applied Biosystems) under the following cycling conditions: 2 min at 95 °C and 40 cycles of 5 sec at 95 °C, 10 s at 60 °C, and 20 s at 72 °C. The QuantStudio Design and Analysis Desktop Software (version 1.4) was used to determine the C_T for each PCR reaction. Primer pairs are shown in Table 5. To ensure no carry-over of DNA into each total purified RNA sample, 100 ng of RNA was used directly as a template without reverse transcription for qPCR using the primer sets described above.

4.4.6 trVLP Assay

Expression plasmids carrying tim-1, T7, NP, VP35, VP30, L, and the tetracistronic minigenome (p4cis-vRNA-hrLuc) carrying luciferase, VP40, GP and VP24 have been previously described^{40,90}. trVLP assays were performed as previously described, with the following changes^{40,41,88}. Passage zero (p0) cells were seeded in 12-well plates and transfected at 50% confluency using Transit LT-1 (Mirus Bio LLC, Madison, WI, USA) with expression plasmids carrying T7-polymerase (125 ng; all amounts per well), the viral proteins NP (62.5 ng), VP35 (62.5 ng), VP30 (37.5 ng), L (500 ng), a tetracistronic minigenome (125 ng), and Firefly luciferase (100 ng) following the manufacturer's instructions. Twenty-four hours prior to infection of p1, p2, p3 and p4 cells, target cells were pre-transfected with expression plasmids carrying NP (62.5 ng), VP35 (62.5 ng), VP30 (37.5 ng), L (500 ng), Tim-1 (125 ng) and either HERC5 (125 ng) or empty vector (125 ng).

4.4.7 Cell Viability Assay

293T cells were co-transfected with pFLAG-VP40, GFP-VP40 or GFP alone, as well as increasing concentrations of pFLAG-HERC5 or empty vector control plasmid. Forty-eight hours post-transfection Cell Counting Kit-8 (CCK-8) (GLP BIO) was used to measure cell viability as per the manufacturer's instructions.

4.4.8 Statistical Analyses

GraphPad Prism v9 was used for all statistical analyses stated in the text. *p* values and statistical tests used are stated in the text where appropriate. *p* values less than 0.05 were deemed significant. Quantification of immunogold labelling for statistical analysis was performed as described³¹.

5 Discussion

This dissertation highlights the potency of the small HERC family of proteins in combating evolutionarily diverse families of viruses. This ongoing battle between restriction factors and viruses has shaped this group of proteins and their function. Although the small HERC family of proteins has been implicated in regulation of cell senescence^{1,2}, cell proliferation³, autophagy⁴, tissue growth and remodeling⁵, regulation of nuclear export^{6,7}, spermatogenesis⁸, as well as several pro and anti-cancer properties^{4,9-15}, their antiviral properties, especially those of HERC3 and HERC4, are less well characterized in humans. Here, we build upon the current knowledge of the antiviral characteristics of the small HERC family of protein with special emphasis on the interferon induced members HERC5 and HERC6. This investigation led to the discovery of a single nucleotide polymorphism in HERC6 which inhibits the production of infections HIV particles, similar to HERC5, the most potent antiviral member of the small HERCs. We found that HERC5 reduces intracellular levels of EBOV VP40 RNA, a mechanism which is antagonized by EBOV GP. This work showcases the small HERCs as a functionally important family of proteins which contribute to the antiviral cellular state. Specifically, it advances the knowledge of HERC5 and HERC6 and their role in antiviral immunity against HIV and EBOV.

5.1 Summary of Findings

Believed to have originated from a gene fusion event which linked an RCC1-like domain (RLD) with a HECT domain, the small HERC family of proteins began with HERC4 over 595 mya. In Chapter 2 we investigated the evolutionary origin and antiviral activities of these proteins to define the protection they provide against pathogens. Based on the available genome assemblies of vertebrates we estimate the emergence of HERC4 was followed by HERC3 approximately 476 mya, HERC6 emerged approximately 430 mya and HERC5 approximately 413 mya (Figure 2.1). Our analysis suggests that the small HERC family has undergone gene duplication events, chromosomal rearrangements, and potential gene loss events over the course of vertebrate evolution.

Closer examination of the amino acid homology of the RCC1-like and HECT domains of the small HERC family revealed that although the amino acid homology is rather low, their predicted structural homology is highly conserved (Figure 2.2). Next, we tested the ability of the small HERC proteins to inhibit HIV. Although we found that HERC3 and HERC4 are not strongly induced by IFN β (Appendix 7) they maintain some inhibitory function at higher levels of expression (Figure 2.3 F and G). As expected, based on the previous findings of the Barr lab^{6,16}, HERC5 potently inhibits intracellular Gag and released viral particles (Figure 2.3 F). Knocking down HERC5, but not HERC3 and HERC4 allowed for enhanced HIV particle production (Figure 2.3 D and E).

Interestingly, HERC6, HERC5s closest relative, did not significantly inhibit HIV particle production or infectivity (Figure 2.3 F and G). This result was further investigated in Chapter 3 of the thesis. Continuing with the exploration of the small HERC family we found that all four members inhibit Rev dependent nuclear export of Gag RNA to varying extents with HERC5 being the most potent (Figure 2.4). To determine whether the antiviral activity of HERC5 has an ancient origin we used a coelacanth HERC5 construct, the oldest vertebrate in which HERC5 was identified. We found that while coelacanth HERC5 and HERC6 cannot inhibit HIV, they retain some antiviral activity against SIV, exhibiting differentia species- and specific- antiviral activity (Figure 2.5). Further investigation of HERC6 revealed that several codons are evolving under strong positive selection (Figure 2.6 C) and that blade 1 of HERC6 is an important determinant of anti-HIV activity (Figure 2.7).

The discrepancy between the antiviral activity of HERC5 and HERC6 while being the most closely related members of the small HERC family was intriguing and led us to investigate the structural differences between these proteins. By comparing the structure of the RLD domain of HERC5 and HERC6 we discovered that blade 1 of HERC6 is folded toward blade 2 while blade 1 of HERC5 is folded away from the rest of the protein structure, a structural change alleviated when the arginine at position 10 and glutamic acid at position 64 were mutated to alanine (Figure 3.1). Interestingly, a small section of the human population possesses a SNP at position 10 of HERC6 (rs111670008) which

substitutes the wildtype arginine with a glycine (R10G). This polymorphism was associated with slower disease progression in a cohort of HIV infected individuals in Uganda (Figure 3.2). We found that overexpression of HERC6 containing the R10G SNP resulted in less infectious HIV particles similar to the effect observed with overexpression of HERC5 (Figure 3.3 C). No difference was observed between HERC6 and HERC6 R10G in Gag content, both intracellular and released in viral particles; viral RNA in the released particles; and nuclear export of unspliced RNA. To better understand the mechanism by which HERC6 R10G overexpression restricts production of infectious HIV particles we performed mass spectrometry analysis on particles produced in cells expressing either HERC6 or HERC6 R10G. GO analysis revealed that in the particles released from the cells expressing HERC6 R10G contained less proteins related to viral transcription, viral gene expression and cotranslational protein targeting to the membrane than those expressing wildtype HERC6 (Figure 3.4 D). Our next step was to determine if attachment of viral particles produced in HERC6 R10G cells was affected compared to those produced in HERC6 expressing cells. Since CADM1, a cell attachment molecule was significantly reduced in the particles isolated from HERC6 R10G cell (Figure 3.4 A) we wondered if neutralization of CADM1 would replicate the loss of infectivity we observed. Unfortunately, treatment with the CADM1 neutralizing antibody did not perform better than the isotype control, suggesting that CADM1 proteins are not important for the infectivity of HIV particles. While this result is not conclusive, it is consistent with other research which has not identified it as an important host protein incorporated in HIV particles and affecting HIV infectivity¹⁷⁻²⁴. Further research is needed to understand the influence of HERC6 R10G on particle infectivity.

Focusing on HERC5 and defining its antiviral properties we asked if HERC5 can inhibit the matrix protein of Ebola virus similar to its ability to inhibit HIV Gag protein¹⁶. While previous studies found that ISGylation of Ebola matrix protein VP40 lead to a decrease in the release of virus-like particles from the cells^{25,26} we aimed to determine the role of HERC5, if any, in the inhibition of Ebola virus. To that end we used a trVLP assay to investigate the effect of HERC5 overexpression on EBOV particle production. Compared

to control cells, HERC5 expression reduced the infectivity of the produced virions over time, an effect correlated with a reduction in GP and VP40 (Figure 4.1). We found that increased amounts of HERC5 reduced both intracellular VP40 protein and virus like particles produced (Figure 4.2 A, D, E and F). Noticing that intracellular VP40 protein levels were reduced, a phenotype not expected if ISGylation of VP40 is inhibiting its ubiquitination and budding from the plasma membrane, we asked if RNA levels of VP40 are unchanged. Quantitative PCR showed that VP40 levels were significantly reduced in HERC5 overexpressing cells compared to control, an effect also observed on other EBOV proteins to a lesser extent (Figure 4.2 H). Using HERC5 domain truncations we determined that the RLD domain of HERC5 is necessary and sufficient for HERC5 mediated restriction of VP40 at both the RNA and protein levels (Figure 4.3). Since the level of VP40 in our trVLP assay did not coincide with the drastic reduction in VP40 protein observed in our RT-qPCR and western blot assays we asked if EBOV proteins may be antagonizing HERC5. We found that both GP and to a lesser extent L protein antagonized HERC5 mediated restriction of VP40 (Figure 4.5). This antagonistic effect was genus specific, as the MARV GP did not inhibit HERC5 mediated restriction of VP40 (Figure 4.4 C and Figure 4.5). These results highlight the multifaceted way HERC5 inhibits EBOV protein expression and the antagonism which does not allow this restriction to combat Ebola virus infections *in vivo*.

5.2 Future directions

The goal of scientific research is to systematically find answers. However, more often than not, research leads to new questions rather than answers. While in this thesis I have illuminated certain aspects of the small HERC family and their workings, several new questions require attention. The world of the small HERC family and their diverse functions remains a largely unexplored one. Several of their functions are inferred from RNA sequencing during various disease states and their contribution to said state and mechanism of action remains a mystery²⁷⁻³⁹. While these studies are important to focus the research on the proteins most affected during the disease states it is important for the development of cures to have a thorough understanding of the workings of these proteins.

Several questions remain unanswered about HERC3 and HERC4 and their ability to inhibit viral pathogens. Although they are not interferon induced in humans it is likely their expression modulated by the state of the tissue where they are expressed. For example, Senegalese sole and Atlantic cod, HERC4 expression is induced by viral infection and dsRNA⁴⁰⁻⁴². Direct testing of the effect these proteins have against diverse viruses will reveal the protection they provide.

Along the same lines HERC6 research has largely been focused on mice where it acts as the main E3 ligase for ISG15. The function of HERC6 independent of ISGylation is likely involved in male fertility in mice but further studies are needed to determine the mechanism of action or whether this translates to human biology⁴³. Additionally, the antiviral properties of HERC6 in humans are understudied. Recently, HERC6 has been identified as an upregulated protein in several transcriptomic studies of viral infection in humans and other mammals⁴⁴⁻⁴⁸. Several questions remain unknown about whether this is linked to the enzymatic activities of the HECT domain of HERC6 or whether, as we found in Chapter 3, this is linked to the RLD domain and its antiviral functions. Further studies are needed to explore the effect of HERC6 R10G and the mechanism of inhibition. Based on our finding in Chapter 3 we suspect that HIV virions produced in HERC6 R10G expressing cells are missing infectivity factors required for the viral infectivity cycle following cell entry. Further studies are needed to identify the mechanism of inhibition as well as the infectivity factor or factors which HERC6 R10G affects. While we did not find that neutralization of CADM1 resulted in reduced HIV infectivity the ability of HERC6 to affect this attachment molecule may have significant implications in a different tissue where both of these molecules are highly expressed, the testis. CADM1 is believed to play a role in the normal differentiation of spermatids and spermatocytes into mature spermatozoa, including in their adhesion to Sertoli cells⁴⁹⁻⁵² while HERC6 knockout mice had severe defects in their sperm sac morphology⁸. Further studies are required to discern if the effect of these protein on male fertility is related.

To better understand the breadth of HERC5s antiviral activity, we researched its ability to inhibit EBOV and its structural protein VP40. Further studies are needed to determine the protagonist-antagonist relationship of HERC5 with other pathogenic viruses. HERC5 is a broadly acting antiviral protein with multiple mechanisms of viral protein restriction. HERC5 can be used as a template for the development of small molecule inhibitors and mimics with the capacity to fight a multitude of viruses both known and yet undiscovered. The use of one antiviral molecule as opposed to the induction of the interferon system can avoid the systemic inflammation and cell damage associated with dysregulation of the interferon response. Knowledge of HERC5s inhibitory mechanisms as well as its antagonism by viral proteins can inform future drug development.

5.3 Concluding Remarks

Enhanced awareness of the small HERC family of proteins will aid in the understanding of diverse cellular function in both healthy and diseased states. Further research implementing novel technologies such as RNA sequencing, single cell transcriptomic and proteomic profiling, as well as high-throughput high-resolution mass spectrometry will enhance the comprehension of this fascinating and important family of proteins and how their regulation effects cellular processes. Knowledge regarding the antiviral activities of the small HERC family of proteins from the effect of HERC4 on fish immunity to the understanding of HERC5 and HERC6 regulation and antagonism by various viruses can lead to the development of small molecule inhibitors and mimics which can aid the immune system in combating viral infection.

Appendix 3: HERC5 but not HERC4 depletes FLAG-tagged VP40 protein in a dose dependent manner

A) 293T cells were co-transfected with plasmids carrying FLAG-tagged VP40 (pFLAG-VP40), VP40-eGFP or just GFP plasmid and increasing concentrations of FLAG-tagged HERC5 (pFLAG-HERC5). Empty vector plasmid was transfected in the condition with 0 μ g of HERC5 plasmid and used to ensure equal amounts of DNA were transfected in each condition. Forty-eight hours post-transfection cell viability was measured using the CCK8 assay. Fold change in absorbance compared to untransfected cells was calculated. The results of 4 independent experiments are shown. **(B)** 293T cells were co-transfected with plasmids carrying VP40-eGFP or just GFP plasmid and increasing concentrations of FLAG-tagged HERC4 (pFLAG-HERC4). Forty-eight hours post-transfection cell viability was measured using CCK8 assay. Fold change in absorbance compared to untransfected cells was calculated. Results of 4 independent experiments are shown. **(C and D)** Cells were transfected as in (A) purified VLPs released into the cell supernatant and intracellular protein were subjected to Western blot analysis using anti-FLAG, anti-VP40 and anti-GAPDH. The average densitometric quantification of VP40 protein bands is shown to the right after normalization to GAPDH levels (\pm S.E.M.). Representative Western blot of four independent experiments is shown. **(E and F)** Cells were transfected as in (B) purified VLPs released into the cell supernatant and intracellular protein were subjected to Western blot analysis using anti-HERC4, anti-VP40 and anti-GAPDH. The average densitometric quantification of VP40 protein bands is shown to the right after normalization to GAPDH levels (\pm S.E.M.). Representative Western blot of four independent experiments is shown.

Appendix 4: HERC5 depletes GFP- and FLAG-tagged VP40 mRNA but not GFP mRNA

293T cells were transfected with HERC5 or control plasmid and GFP-tagged VP40, Flag-tagged VP40, or GFP plasmid. mRNA levels for VP40 and GFP were measured 24 hours post transfection using qRT-PCR. The data shown represent the average (\pm S.E.M.) of 4 independent experiments. **** $p < 0.0001$, * $p \leq 0.05$, ns (not significant) $p > 0.05$

Region	Observed gold count, G_0	Point count, P	Expected gold count, G_e	G_0/G_e	X^2	X^2 as %
Particles + plasma membrane	30	15	4	7.75	176.43	66.94
Cytoplasm + nucleus	35	49	13	0.71	39.62	15.03
Non-particle + non-cell	1	192	53	0.02	47.52	18.02
TOTAL	70	256	70		263.57	100

Appendix 5: Quantification of 5nm gold particle-labeled anti-GFP in cells expressing HERC5 and VP40-eGFP.

For $X^2= 176.43$ and $df=2$, $P < 0.0001$ (X^2 analysis). The gold labeling distribution is significantly different from random. Only the particles + plasma membrane region ($G_0/G_e= 7.75$, $X^2= 66.9\%$ of total) meets the two criteria for being preferentially labeled ($(G_0/G_e) \geq 1$ and $X^2 > 10\%$ of total).

Appendix 6: Quantification of Small HERC mRNA and protein expression when overexpressed through transfection or induced by IFN β .

293T cells were either transfected (**A to D and I to P**) with increasing concentrations of HERC plasmid as indicated or treated with increasing amounts of IFN β (**E to H, Q and R**). mRNA levels (A to H) were measured via qRT-PCR. I to L, Q and R, shows representative western blot of protein expression. (**M to P**) quantification of 3 trials of the HERC protein.

Curriculum Vitae

Name: Ermela Paparisto

Post-secondary Education and Degrees: University of Toronto (Scarborough)
Toronto, Ontario, Canada
2009-2013 Honors BSc. Human Biology and Psychology

The University of Western Ontario
London, Ontario, Canada
2014-2023 Ph.D. Microbiology & Immunology

Honors and Awards: RGE Murray Scholarship in Microbiology and Immunology
2017-2019

Graduate (>6 Months) Poster Presentation Award
Infection and Immunity Research Forum
2015

Related Work Experience Teaching Assistant (MNI 2500, MNI3820, BIO1001)

2016-2019

Publications:

Paparisto E, Woods MW, Coleman MD, Moghadasi SA, Kochar DS, Tom SK, Kohio HP, Gibson RM, Rohringer TJ, Hunt NR, Di Gravio EJ, Zhang JY, Tian M, Gao Y, Arts EJ, Barr SD. **Evolution-Guided Structural and Functional Analyses of the HERC Family Reveal an Ancient Marine Origin and Determinants of Antiviral Activity.** *J Virol.* 2018 Jun 13;92(13):e00528-18. doi: 10.1128/JVI.00528-18. PMID: 29669830; PMCID: PMC6002735.

Paparisto E, Hunt NR, Labach DS, Coleman MD, Di Gravio EJ, Dodge MJ, Friesen NJ, Côté M, Müller A, Hoenen T, Barr SD. **Interferon-Induced HERC5 Inhibits Ebola Virus Particle Production and Is Antagonized by Ebola Glycoprotein.** *Cells.* 2021 Sep 13;10(9):2399. doi: 10.3390/cells10092399. PMID: 34572049; PMCID: PMC8472148.

Mathieu NA, **Paparisto E**, Barr SD, Spratt DE. **HERC5 and the ISGylation Pathway: Critical Modulators of the Antiviral Immune Response.** *Viruses.* 2021 Jun 9;13(6):1102. doi: 10.3390/v13061102. PMID: 34207696; PMCID: PMC8228270.

Ajoge HO, Kohio HP, **Paparisto E**, Coleman MD, Wong K, Tom SK, Bain KL, Berry CC, Arts EJ, Barr SD. **G-Quadruplex DNA and Other Non-Canonical B-Form DNA Motifs Influence Productive and Latent HIV-1 Integration and Reactivation Potential.** *Viruses.* 2022 Nov 11;14(11):2494. doi: 10.3390/v14112494. PMID: 36423103; PMCID: PMC9692945.
