## Abstract

Since erythrocytes release the vasodilator adenosine triphosphate (ATP) in an oxygen ( $O_2$ ) dependent manner, erythrocytes are proposed to play a central role in  $O_2$  regulation. This ATP signaling mechanism is proposed to be most efficient in the capillaries due to the short diffusion distance to the electrically coupled endothelium which communicates directly with arterioles. We hypothesize that capillaries are able to signal upstream arterioles for changes in erythrocyte supply rate in response to changes in capillary erythrocyte  $O_2$  saturation ( $SO_2$ ) through  $SO_2$ -dependent ATP signaling. To test this hypothesis, we have developed a micro-delivery system for controlling the  $O_2$  availability to highly localized regions of the micro-vascular bed within intact tissue (rat Extensor Digitorum Longus). This approach allows for altering the erythrocyte  $SO_2$  level in selected capillaries while simultaneously recording blood flow changes using *in vivo* video microscopy (IVVM). Three designs for the  $O_2$  exchange outlet were tested. Gas with varying levels of  $O_2$  was directly transported to specific locations on the surface of the muscle through a circular micro-outlet ( $\sim 100 \mu\text{m}$  in diameter), a square micro-slit ( $200 \mu\text{m} \times 200 \mu\text{m}$ ), or a rectangular micro-slit ( $1000 \mu\text{m}$  wide  $\times 200 \mu\text{m}$  long) patterned in ultrathin glass/plastic sheet using state-of-the-art microfabrication techniques. Video sequences captured during oscillating  $O_2$  levels were processed for changes in capillary hemodynamic parameters and erythrocyte  $SO_2$ . Our results indicated that a sufficient number of capillaries need to be affected by local  $O_2$  perturbations in order to elicit micro-vascular responses.. Although erythrocyte  $SO_2$  can be measured in single capillaries flowing over an  $O_2$  micro-outlet down to  $100 \mu\text{m}$  in diameter, at least 3-4 capillaries needed to be stimulated within a branching capillary network in order to induce conducted micro-vascular responses. Since the measured supply rate responses show strong

linear correlation with capillary erythrocyte  $\text{SO}_2$ , the responses are suggested to be linked to an  $\text{SO}_2$ -dependent signaling mechanism by the erythrocyte, which further supports our hypothesis. Based on the results, we have successfully designed a novel micro-delivery device for localized  $\text{O}_2$  exchange at the microvasculature to understand fundamental mechanisms of micro-vascular regulation of  $\text{O}_2$  supply.

**Keywords:** Adenosine triphosphate (ATP), oxygen saturation ( $\text{SO}_2$ ), *in vivo* video-microscopy (IVVM), microcirculation, microfabrication,  $\text{O}_2$  micro-delivery, hemodynamics, conducted microvascular response.

## Co-Authorship Statement

Chapter 1 entitled “Understanding oxygen transport and microvascular regulation” was written by Nour W. Ghonaim with input from Dr. Christopher G. Ellis and Dr. Daniel Goldman. Chapter 2 entitled “A Micro-delivery Approach for Studying Microvascular Responses to Localized Oxygen Delivery” was written by Nour W. Ghonaim with input from Dr. Christopher G. Ellis, Dr. Daniel Goldman, and Dr. Jun Yang. The O<sub>2</sub> micro-delivery system was designed by Nour W. Ghonaim, Dr. Leo W.M. Lau, Dr. Daniel Goldman, Dr. Christopher G. Ellis, and Dr. Jun Yang. The micro-fabrication of the O<sub>2</sub> micro-outlets in ultrathin glass was fully conducted by Nour W. Ghonaim at the nanofabrication laboratory at Western University, Canada. The *in vivo* experiments with the O<sub>2</sub> micro-delivery system were fully conducted by Nour W. Ghonaim under the supervision of Ms. Stephanie Milkovich. Data analysis was fully performed by Nour W. Ghonaim with technical assistance by Ms. Stephanie Milkovich and with intellectual input on data interpretation from Dr. Christopher G. Ellis and Dr. Jun Yang. The mathematical model simulating the PO<sub>2</sub> tissue distribution from O<sub>2</sub> micro-outlets was developed by Dr. Daniel Goldman and simulations were run by Nour W. Ghonaim. Also, Dr. Goldman wrote the section titled “Mathematical Modeling of the PO<sub>2</sub> Distribution Profile”. Chapter 3 entitled “Modeling steady state SO<sub>2</sub>-dependent changes in capillary ATP concentration using novel O<sub>2</sub> micro-delivery methods” was written by Nour W. Ghonaim with input from Dr. Graham M. Fraser, Dr. Christopher G. Ellis, Dr. Jun Yang, and Dr. Daniel Goldman. The computational models that describe O<sub>2</sub> and ATP transport in the capillaries were developed by Dr. Daniel Goldman. Simulations were run by Nour W. Ghonaim. Data analysis was performed by Nour W. Ghonaim and Dr. Graham M. Fraser with intellectual input on data interpretation from Dr. Christopher G. Ellis,

Dr. Daniel Goldman, Dr. Graham Fraser, and Dr. Jun Yang. Chapter 4 entitled “Conducted Microvascular Response to Localized Oxygen Delivery using A Novel Micro-delivery Approach” was written by Nour W. Ghonaim with input from Dr. Christopher G. Ellis and Dr. Jun Yang. The O<sub>2</sub> micro-delivery system was designed by Nour W. Ghonaim, Dr. Leo W.M. Lau, Dr. Daniel Goldman, Dr. Christopher G. Ellis, and Dr. Jun Yang. The micro-fabrication of the O<sub>2</sub> micro-outlets in ultrathin glass was fully conducted by Nour W. Ghonaim at the nanofabrication laboratory at Western University, Canada. The micro-fabrication of the O<sub>2</sub> micro-slit in ultrathin plastic was conducted by Nour W. Ghonaim with the help of Hugo W. Reshef and Mohammad Tauhiduzzaman at the National Research Council, Research Park, London, Ontario. The *in vivo* experiments with the O<sub>2</sub> micro-delivery system were fully conducted by Nour W. Ghonaim. Data analysis was fully performed by Nour W. Ghonaim with intellectual input on data interpretation from Dr. Christopher G. Ellis, Dr. Daniel Goldman, and Dr. Jun Yang. Chapter 5 entitled “General Discussion” was written by Nour W. Ghonaim with input from Dr. Christopher G. Ellis and Dr. Daniel Goldman.

## Acknowledgments

First I would like to thank my amazing supervisors Professor Jun Yang and Professor Christopher Ellis for all their guidance and support throughout my Doctoral research. I am grateful for their time and understanding and I appreciate their determination to motivate me to do excellent work. I am very proud to have had the privilege to be their student and trainee. My respect for their intellect and constructive supervision is beyond that of a student to a supervisor. They will always continue to inspire me to be the best researcher and supervisor I can be. Also, I would like to thank my advisory committee members Professor Leo Lau and Professor Daniel Goldman for their advice and guidance.

I would like to thank my lab members, colleagues and technical instructors for being an amazing team and for all the help, training and support. Specifically, I would like to thank Ms. Stephanie Milkovich from Dr. Ellis' laboratory for spending countless hours training and assisting me in running my experimental procedures and data analysis. I also thank Dr. Graham Fraser from Dr. Ellis' laboratory for his help in data analysis and producing figures presented in Chapter 3. I would like to thank the members of the nanofabrication facility at Western University as well as Dr. Mei Liu, Dr. Tingjie Li, and Dr. Charles Guo from Dr. Yang's laboratory for their training and input on microfabrication techniques and microfluidic device design.

Finally, this work would have never been accomplished without the invaluable support and motivation from my parents, my sisters, and my wonderful husband. I cannot thank them more for their kindness and incentive throughout the progression of my PhD work and thesis. I admire my husband, Zaid, for continuing to push me towards success in my career and

throughout my PhD despite the distance that separated us. To my beloved family and husband I dedicate this thesis.

## 1 Understanding oxygen transport and microvascular regulation

### 1.1 Introduction

The mechanisms regulating oxygen (O<sub>2</sub>) supply in microvascular networks to meet tissue O<sub>2</sub> demand comprise one of the most critical physiological regulation systems. The understanding of O<sub>2</sub> transport and regulation is fundamental to the understanding of the pathophysiology underlying several microvascular diseases. The increased diffusion distance of O<sub>2</sub> in sepsis and the compromised vascular reactivity in type II diabetes eventually lead to tissue hypoxia and organ failure (Ellis et al. 2002; 2010, Goldman et al. 2004, Sprague et al. 2006; 2010). In the microcirculation, O<sub>2</sub> is transported by erythrocytes bound to hemoglobin and is unloaded near metabolically active tissue down its partial pressure (PO<sub>2</sub>) gradient. The hemoglobin molecule has four subunits each of which contains an O<sub>2</sub> binding site. Hemoglobin binds O<sub>2</sub> in a cooperative manner such that binding of O<sub>2</sub> to one of the subunits facilitates binding by the others. When all four binding sites are occupied by O<sub>2</sub>, hemoglobin is in its fully saturated state. Due to the cooperative binding, the hemoglobin O<sub>2</sub> saturation (SO<sub>2</sub>) level is related to blood PO<sub>2</sub> in a sigmoidal relationship described by the Hill Equation (Hill 1910):

$$S(P)=P^n/(P^n+P_{50}^n)$$

Where,  $S(P)$  is the hemoglobin SO<sub>2</sub>,  $P$  is blood PO<sub>2</sub>,  $P_{50}$  is blood PO<sub>2</sub> at 50% SO<sub>2</sub>, and  $n$  is the Hill coefficient, which describes cooperativity of binding.

This chapter provides a summary of the literature describing the theories and mechanisms by which O<sub>2</sub> supply and demand are matched and the possible role of the erythrocyte through O<sub>2</sub> saturation (SO<sub>2</sub>)-dependent ATP release. Then, the chapter will present a review of the techniques and mathematical models developed for investigating SO<sub>2</sub>-dependent ATP signaling both *in vivo* and *in vitro*. Finally, findings from recent studies suggesting the capillary bed as the site for SO<sub>2</sub>-dependent ATP release will be presented.

## **1.2 Matching oxygen supply and demand: Where is the sensor?**

In 1919, over 90 years ago, August Krogh along with his colleague, K. Erlang, developed a mathematical model to describe regulation of O<sub>2</sub> transport to metabolic tissue. According to Krogh's model, O<sub>2</sub> loss only occurs in the capillary bed with each capillary supplying O<sub>2</sub> radially to the surrounding cylindrical tissue volume "the Krogh cylinder" (Krogh, 1919). In this model, both O<sub>2</sub> diffusivity and tissue O<sub>2</sub> consumption rate were assumed to be constant (Krogh, 1919). The model suggested that capillary density has to be constantly adjusted to match O<sub>2</sub> demand (Krogh, 1919).

In 1970, B.R. Duling and R.M. Berne demonstrated that longitudinal O<sub>2</sub> partial pressure (PO<sub>2</sub>) gradients exist in the arterioles and that substantial O<sub>2</sub> diffusional loss occurs across the arteriolar wall and other locations along the microvasculature (Duling and Berne 1970). Studies on different animal models and tissue preparations by various groups confirmed these findings and reported the establishment of periarteriolar PO<sub>2</sub> gradients prior to reaching the capillaries, which may be partially due to diffusional exchange of O<sub>2</sub> between micro-vessels (Swain and Pittman 1989, Ellsworth and Pittman

1990, Stein et al. 1993, Ellsworth et al. 1994, Tsai et al. 2003). In arterioles, O<sub>2</sub> diffusional loss across the wall causes the red blood cells (RBCs) nearest the wall to have relatively lower SO<sub>2</sub> than those near the center line (Ellsworth and Pittman 1986, Carvalho and Pittman 2008). Plasma skimming would result in uneven erythrocyte distribution at bifurcations (Pries et al. 1996), which leads to the observed heterogeneity in capillary SO<sub>2</sub> and supply rate (Tyml et al. 1981, Ellis et al. 1994). Since capillary perfusion alone is not indicative of proper O<sub>2</sub> supply, the Krogh model cannot fully account for the complexity of micro-vascular O<sub>2</sub> regulation.

A more sensitive and local O<sub>2</sub> regulation mechanism must exist in order to tightly control the distribution of erythrocytes to capillaries with varying O<sub>2</sub> environments (Ellis et al. 2005; 2012, Ellsworth et al. 2009). Since the myogenic response (leading to changes in vascular wall tension) and the flow response (leading to changes in shear stress) are independent of changes in the local O<sub>2</sub> content, they cannot be proposed in the primary regulation of O<sub>2</sub> supply (Ellis et al. 2012). Also, although changes in tissue metabolism will trigger O<sub>2</sub> supply rate changes, it is unlikely that under normal physiological conditions, the regulatory system will delay its response until the tissue becomes hypoxic (Ellis et al. 2012). The system has to constantly adjust and maintain a homogenous O<sub>2</sub> supply and erythrocyte distribution across the micro-vascular bed. This demands a highly localized sensory mechanism, hence the question investigated by several research groups: “where is the O<sub>2</sub> sensor?”

Some groups have suggested micro-vessels or the cells comprising vascular walls (smooth muscle cells or endothelial cells) might act as vascular O<sub>2</sub> sensors (Pittman and Duling 1973, Duling 1974, Jackson and Duling 1983, Jackson 1987, Ellsworth et al.

1988; 1990; 1994, Hester 1993, Messina et al 1994, Pries et al. 1995). Others have suggested the sensor is localized in the tissue surrounding the micro-vessels (parenchymal cells) (Haddy and Scott 1968, Harder et al. 1996). Recently, it has been proposed that the erythrocyte itself may act as a vascular sensor and a key regulator of O<sub>2</sub> supply. This was based on the observation by Stein et al. (1993), that O<sub>2</sub> content (proportional to SO<sub>2</sub>) is more important than PO<sub>2</sub> in generating a micro-vascular response. Since O<sub>2</sub> content reflects the status of hemoglobin, carried by the erythrocytes, which traverse micro-vessels experiencing varying PO<sub>2</sub> environments, the erythrocyte was suggested as the vascular PO<sub>2</sub> sensor and effector (Ellsworth et al. 1995, Jia et al. 1996).

There are three mechanisms suggested by which the erythrocyte may act on the micro-vasculature. Stamler et al. (1997) proposed the S-nitroso (SNO) group in micro-vascular signaling. The low molecular weight nitroso group is carried on the cysteine (cys93) residue of the hemoglobin molecule. Under low PO<sub>2</sub> conditions, the conformational change associated with the desaturation of hemoglobin decreases the binding affinity of SNO to hemoglobin. The released SNO from saturated hemoglobin is proposed to act as a potent vasodilator (Jia et al. 1996, Stamler et al. 1997). The measured venous concentrations of SNOs are much less than in the arterial end which suggests these groups are picked up in the lungs when O<sub>2</sub> levels are high. Despite the presence of some evidence to support the above hypothesis (Liu et al. 2004, Stamler et al. 1997), the role of SNO *in vivo* remains unclear and the accuracy of SNO measurements from biological samples is questionable (Patel et al. 1999, Gladwin and Schechter 2004, Gladwin et al. 2003). Some groups also have suggested that deoxyhemoglobin may act as a nitrite

reductase converting nitrite to NO, which is known to play an important role in micro-vascular signaling (Patel et al. 1999, Cosby et al. 2003, Gladwin et al. 2004). Although this mechanism suggests the erythrocyte may act locally to vasodilate arterioles under low SO<sub>2</sub> conditions, it would lack the temporal resolution required to rapidly and tightly control erythrocyte distribution (Ellsworth et al. 2009). Finally, no evidence has been provided yet to elucidate the involvement of either of the above mentioned mechanisms in conducted micro-vascular response, which would be necessary to integrate the response across the arteriolar tree as well as enable signaling from the capillary bed and venular tree to regulate arteriolar blood flow distribution (Ellsworth et al. 2009).

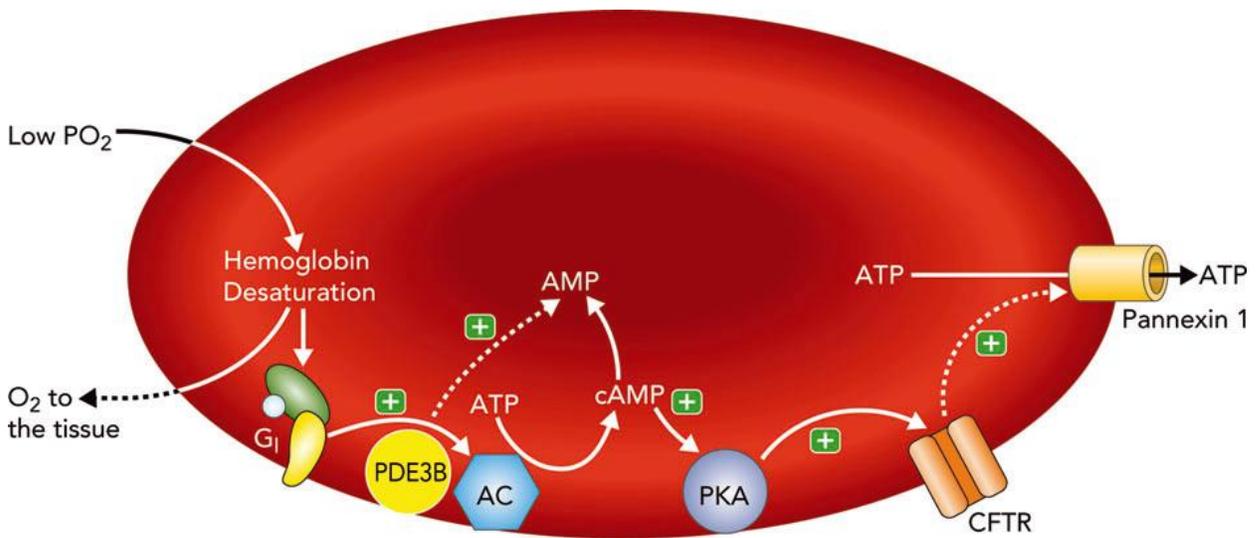

The third mechanism involves SO<sub>2</sub>-dependent adenosine triphosphate (ATP) release from the erythrocyte. ATP is known to be a potent vasodilator and is found in erythrocytes in millimolar concentrations (Miseta et al. 1993). ATP was shown to be released from the erythrocyte under different stimuli including hypoxia and hypercapnia (Bergfeld and Forrester 1992), decrease in pH (Ellsworth et al. 1995), and due to mechanical deformation (Sprague et al. 1996; 1998; 2006). Also, injection of ATP into the vascular lumen was shown to trigger a vaso-dilatory response (McCullough et al. 1997, Collins et al. 1998), which is proposed to be initiated by ATP binding to intraluminal purinergic receptors (P<sub>2Y</sub>) (Needham et al. 1987, Rubino et al. 1995, Corr and Burnstock 1996, Malmstro et al. 1999, Wihlborg et al. 2003). In 2001, Jagger et al. (2001) showed that ATP efflux from the erythrocyte is linearly related to hemoglobin SO<sub>2</sub>. The optimal response was found to be near the animal's P<sub>50</sub> (Sprague and Ellsworth 2012); that is PO<sub>2</sub> at 50% SO<sub>2</sub>. The linear relationship between ATP efflux and SO<sub>2</sub> lead Jagger et al. to suggested that ATP release is elicited by the conformational change of hemoglobin as it

de-saturates (Jagger et al 2001; Ellsworth et al. 2009). To test this hypothesis, Jagger et al (2001) exposed erythrocytes to zero PO<sub>2</sub> in the presence of sufficient carbon monoxide to keep the hemoglobin molecule in its fully saturated state. With zero O<sub>2</sub> but hemoglobin fully saturated, there was no ATP efflux confirming that the conformational change of hemoglobin elicits the ATP release. The association of hemoglobin SO<sub>2</sub> to ATP release was further confirmed by several human studies (Roach et al. 1999, González-Alonso et al. 2002; 2006). Recently, studies have demonstrated that patients with type II diabetes, a medical condition characterized by micro-vascular dysfunction, suffer defects in the release of ATP (Sprague et al. 2006). Also, erythrocytes from human and animal models of pre-diabetes have been shown to suffer attenuated release of ATP in response to decreased O<sub>2</sub> levels (Hanson et al. 2009, Ellis et al. 2010). The release of ATP by the erythrocyte in response to various stimuli transformed our perspective of the erythrocytes being merely O<sub>2</sub> carriers to being vascular sensors actively involved in the regulation of micro-vascular O<sub>2</sub> supply.

### **1.3 Erythrocyte SO<sub>2</sub>-dependent conducted ATP signaling**

The mechanism that links the drop in SO<sub>2</sub> to controlled ATP release from the erythrocyte is not yet fully elucidated (Ellsworth et al. 2009). However, it is suggested that conformational changes in the hemoglobin molecules bound to the erythrocyte membrane as they desaturate (Jagger et al. 2001, Wan et al. 2008; Sridharan et al. 2010b; Forsyth et al. 2011) directly activate the heterotrimeric Gi protein or some other component in the ATP release pathway described by Sprague's group (Olearczyk et al. 2001; 2004,

Sprague et al. 1998; 2002; 2006) (Figure 1.1). Activation of Gi protein is known to increase adenylyl cyclase (AC) activity (Federman et al. 1992, Bayewitch et al. 1998), which was shown to be a component in the ATP release pathway (Sprague et al. 1998; 2001, 2008). Activation of AC increases intracellular cAMP level, which is modulated by phosphodiesterase 3B (PDE3B) activity (Hanson et al. 2008, Adderley et al. 2010a; 2010b). cAMP activates protein kinase A (PKA) (Sprague et al. 2001), which subsequently leads to activation of the cystic fibrosis trans-membrane conductance regulator (CFTR) (Sprague et al. 1998). ATP is suggested to be eventually released from the erythrocyte through the pannexin 1 channel (Sridharan et al. 2010a) (Figure 1.1). The release of ATP from the erythrocyte through the described pathway is shown to be rapid; in the order of 150-500 ms (Dietrich et al. 2000, Wan et al. 2008).

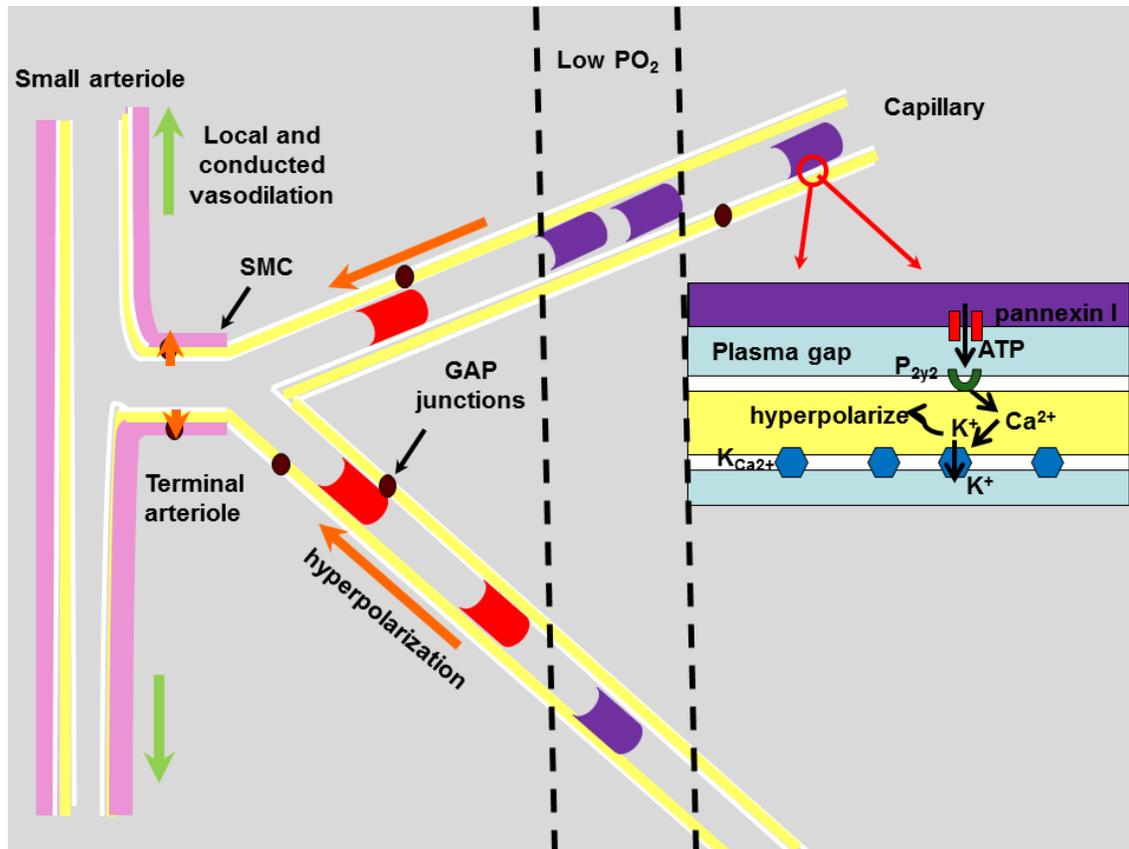

**Figure 1.1** Proposed SO<sub>2</sub>-dependent ATP release signaling pathway from the erythrocyte. Conformational changes associated with desaturation of membrane-bound hemoglobin mechanically activate the Gi heterotrimeric G protein. Consequently, the Gi

protein activates Adenylyl Cyclase (AC) increasing intracellular cAMP concentrations. The level of cAMP in the cell is modulated by phosphodiesterase function (PDE3B). Increase in cAMP activates protein kinase A (PKA) followed by cystic fibrosis transmembrane conductance regulator (CFTR) activation. ATP is eventually released from the cell through the pannexin 1 channels. Figure is reproduced from Sprague and Ellsworth 2012 with permission.

Released ATP is known to bind to P<sub>2y</sub> receptors (You et al. 1999, Horiuchi et al. 2001) on the vascular endothelium, which then promotes the release of Ca<sup>2+</sup> from the endoplasmic reticulum (Campbell et al. 1996) (Figure 1.2). Ca<sup>2+</sup> release mediates the synthesis and release of vasodilators such as nitric oxide (NO) as well as metabolites of arachidonic acid (You et al. 1997; 1999). In order for the capillary erythrocyte supply rate to be increased in response to released ATP, the signal must be conducted upstream to the arteriolar tree. Epoxyeicosanoic acids (EETs), products of arachidonic acid, are known to activate Ca<sup>2+</sup> activated K<sup>+</sup> channels, which results in the hyperpolarization of endothelial and smooth muscle cells (SMCs) (Campbell et al. 1996, Dietrich et al. 1998, Fukao et al. 2001) (Figure 1.2). The hyperpolarization can be conducted to adjacent cells in the endothelium through gap junctions and to SMCs through the myoendothelial junction resulting in local and conducted vasodilation (Segal et al. 1989, Segal and Duling 1989). The ATP signal is proposed to be controlled through negative feedback mechanisms by NO or breakdown products of ATP (Olearczyk et al. 2004b, Wang et al. 2005), or through degradation by ecto-ATPases (Knowles 2011, Melani et al. 2012). The magnitude of the micro-vascular response to ATP signaling is suggested to be related to

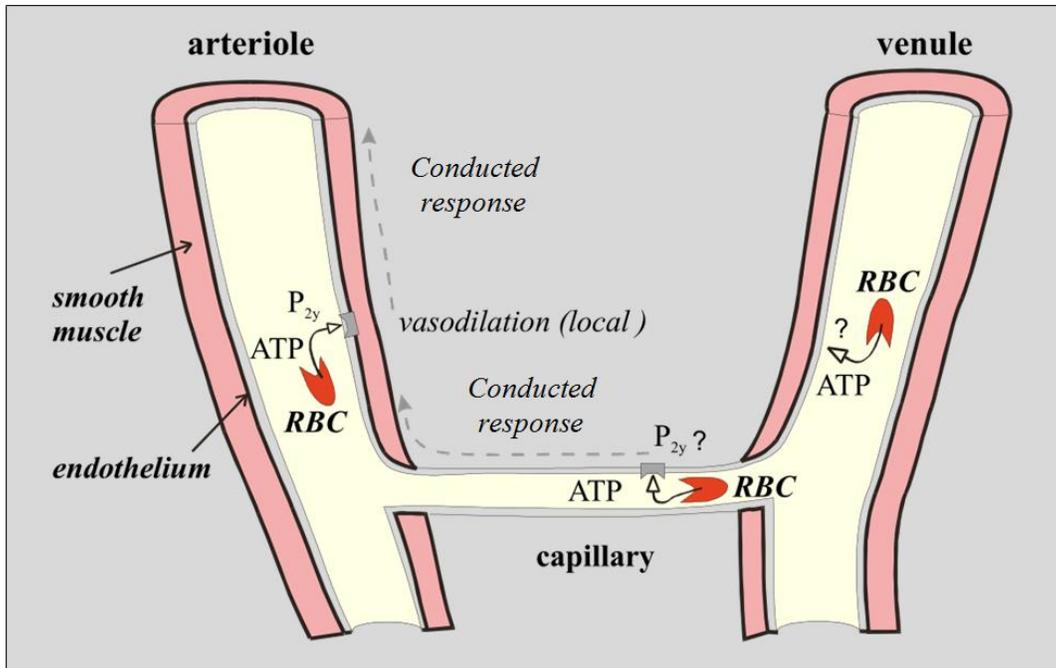

the extent of the hyperpolarization signal and to the number of endothelial cells activated (Ellis et al. 2012). Some of the factors that would influence ATP signaling to the vascular endothelium include: the time it takes for ATP to be released following an SO<sub>2</sub> drop, the distance ATP has to travel from the erythrocyte membrane to the P<sub>2y</sub> receptors, and the time it takes to degrade ATP by ecto-ATPases thus eliminating the signal. In order for SO<sub>2</sub>-dependent ATP release to be a key regulator of O<sub>2</sub> supply, the ATP signaling mechanism must be efficient (Ellis et al. 2012).

**Figure 1.2** ATP-mediated conducted vasodilation response. ATP released from deoxygenated erythrocytes binds and activates purinergic (P<sub>2y</sub>) receptors on the vascular endothelium. This stimulates Ca<sup>2+</sup> release from the endoplasmic reticulum which eventually results in the activation of Ca<sup>2+</sup> activated K<sup>+</sup> channels leading to endothelial hyperpolarization. The hyperpolarization is conducted to adjacent endothelial cell through gap junctions and finally to arteriolar smooth muscle cells through myo-endothelial gap junctions. Hyperpolarization of smooth muscle cells results in local and conducted vasodilation and consequent increases in the supply rate of oxygenated erythrocytes to meet the demand of the hypoxic region.

## **1.4 The capillary bed as the site for erythrocyte SO<sub>2</sub>-dependent ATP release**

There is a lot of debate as to the site of ATP release and action (Figure 1.3). It has been suggested that ATP is mainly released in the arterioles such that the activation of endothelial cells would result in immediate vasodilation of adjacent SMCs (Duling and Berne 1970, Duling 1974, Jackson 1987). However, the relatively short erythrocyte transit times would largely compromise the temporal and spatial localization of the signal. Also, due to the parabolic flow profile in arterioles, only those cells nearest the arteriolar wall will experience SO<sub>2</sub> drops and hence be involved in ATP release. Cells flowing through the centerline will experience smaller a SO<sub>2</sub> drop and will participate to a lesser extent in ATP signaling (Ellis et al. 2012). Venues were also suggested to play a role in O<sub>2</sub> regulation. The increase in hematocrit at the venues combined with low SO<sub>2</sub> level would result in a large amount of ATP release and a strong conducted vasodilatory signal as modeled in Arciero et al. (2008). However, since venues collect erythrocytes with a wide range of SO<sub>2</sub> values from various upstream capillaries, the conducted signal would be highly unspecific and may only contribute to controlling regional blood flow rather than to individual capillary networks (Ellis et al. 2012)

**Figure 1.3** Schematic showing possible sites for SO<sub>2</sub>-mediated ATP release and action in the microvasculature. Figure reproduced from Ellsworth et al. 1995.

Recently, capillaries have been hypothesized as the major site for SO<sub>2</sub>-dependent ATP release and signaling (Ellis et al 2012). Capillaries are composed of endothelial cells which are known to be electrically coupled and communicating (Dietrich, 1989, Dietrich and Tyml, 1992, Song and Tyml 1993, Collins et al., 1998, Bagher and Segal, 2011). Erythrocytes traverse capillaries at relatively longer transit times, which better localizes the ATP signal. Also, the diffusion distance of ATP to the capillary endothelium is < 1 μm. Therefore, depending on the capillary diameter as well as the thickness of the erythrocyte and endothelial coating there might be a direct transfer of ATP from the pannexin 1 channel on the erythrocyte to the P<sub>2y</sub> receptors on the vascular endothelium (Ellis et al. 2012). This implies more efficient and localized SO<sub>2</sub>-dependent ATP

signaling in the capillary bed. It should be noted that in the capillaries, the erythrocyte supply rate (erythrocytes per second) is anticipated to have a great effect on the magnitude of ATP signal (Ellis et al. 2012). At an erythrocyte velocity of 100  $\mu\text{m}/\text{sec}$ , each erythrocyte would stimulate the same endothelial cell ( $\sim 104 \mu\text{m}$  long) for  $\sim 1$  sec (Ellis et al. 2012). The number of erythrocytes stimulating a single endothelial cell per second would be determined by the supply rate level. For instance, at a supply rate of 10 RBC/sec, approximately 10 erythrocytes would be stimulating the same endothelial cell in 1 sec. At higher velocities, a larger number of endothelial cells would be activated per unit of time, each of which will contribute to the conducted signal (Ellis et al. 2012).

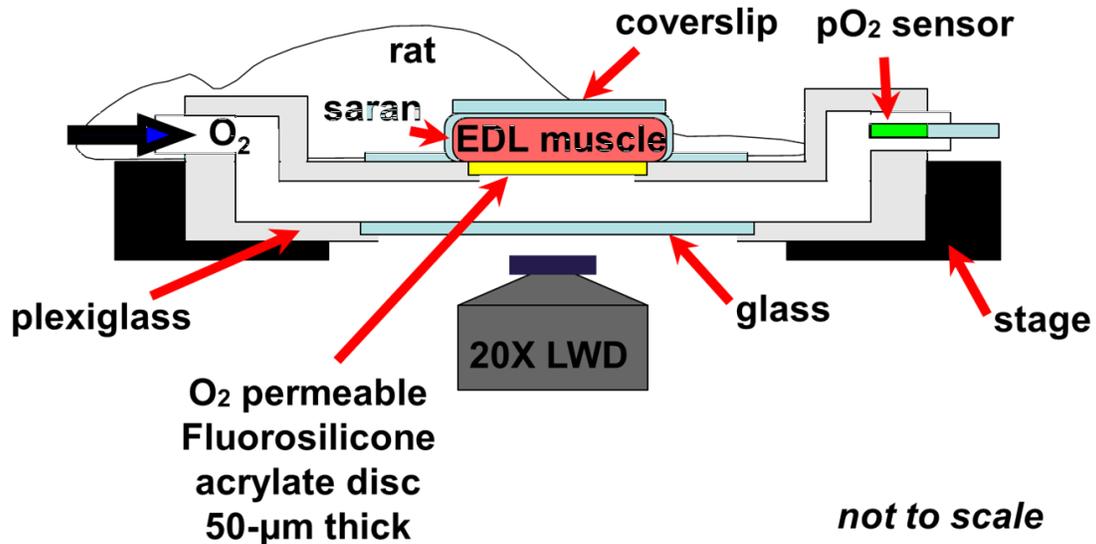

## **1.5 Techniques developed for investigating micro-vascular response in the capillary bed *in vivo***

Micro-vascular responses to tissue  $\text{PO}_2$  perturbations, characterized by changes in the erythrocyte supply rates, have commonly been investigated using *in vivo* video-microscopy (IVVM) techniques (Dewhirst et al. 2000, Varghese et al. 2005, Ellis et al. 2010). IVVM allows for monitoring and recording real-time changes in micro-vascular blood flow properties (Dewhirst et al. 2000, Varghese et al. 2005, Ellis et al. 2010). Typically, studies involved altering  $\text{PO}_2$  levels in a superfusion solution equilibrating the surface of a tissue or a vessel (Duling 1974, Jackson and Duling 1983). However, using superfusion solutions may result in washing away substances or signaling molecules from tissue surface, which would affect micro-vascular responses (Ellis et al. 2012). Also, the relatively low solubility of  $\text{O}_2$  in saline solution presents another limitation of using

superfusion solutions as a medium for O<sub>2</sub> delivery or removal since erythrocytes flowing in capillaries have a much greater O<sub>2</sub> carrying capacity.

In order to overcome some of the drawbacks of using the superfusion technique, Dr. Chris Ellis' laboratory, at Western University, Canada, developed a gas exchange chamber in which the full bottom surface of the rat extensor digitorum longus (EDL) muscle is exposed to PO<sub>2</sub> perturbations (Jagger et al. 2005, Ellis et al. 2010; 2012, Ghonaim et al. 2011) as shown in Figure 1.4. Using this method, O<sub>2</sub> is delivered to or removed from the tissue surface through a 4 mm x 10 mm outlet covered with fluorosilicone acrylate O<sub>2</sub>-permeable membrane of 50 µm in thickness, while maintaining constant CO<sub>2</sub> and temperature. The gas exchange chamber is inserted into the viewing platform of an inverted light microscope and is connected to computer-controlled flow meters. This allows for real-time videos of blood flow changes in the microcirculation to be recorded while simultaneously controlling O<sub>2</sub> levels in the chamber (Figure 1.4). The advantage of using this technique is that O<sub>2</sub> is delivered in a gas mixture bringing the system closer to physiological conditions without washing away other signalling molecules. Furthermore, by setting the minimum chamber O<sub>2</sub> level at 2% (15-mmHg), there should be no or minimal effect on tissue metabolism such that the resulting microvascular flow response can be attributed solely to changing O<sub>2</sub> levels. The fluorosilicone acrylate membrane is highly permeable to O<sub>2</sub> (O<sub>2</sub> permeability coefficient = 100 Barrers, where 1 Barrer = 10<sup>-11</sup> (cm<sup>3</sup> O<sub>2</sub> STP) cm<sup>2</sup> cm<sup>-3</sup> sec<sup>-1</sup> mmHg<sup>-1</sup> (Comyn 1985)) hence, the delivered O<sub>2</sub> would have greater effect on the tissue PO<sub>2</sub> level relative to using liquid media. However, in this setup, the O<sub>2</sub> outlet was designed to have the EDL muscle dimensions, hence the technique measures the collective response of stimulating the full

micro-vascular bed by  $O_2$  delivery or removal. In order to investigate the response to stimulating selected capillaries in the microvasculature, the area of the  $PO_2$  perturbations needs to be limited.

**Figure 1.4** *In vivo* video microscopy (IVVM) full gas exchange chamber experimental setup. The chamber is connected to computer controlled flow meters and is inserted into the viewing platform of an inverted microscope. The extensor digitorum longus (EDL) muscle of the rat is surgically exposed and positioned surface down on the viewing platform. Oxygen ( $O_2$ ) is delivered in a gas mixture to the muscle surface through an outlet with dimensions proportional to the *in situ* dimensions of the EDL muscle.  $O_2$  levels in the chamber are measured and monitored using a fiber-optic oxygen sensor probe. The tissue is trans-illuminated, and hemodynamic responses are recorded and analyzed as  $O_2$  levels are simultaneously oscillated while maintaining constant  $CO_2$  and temperature.

Song and Tyml (1993) investigated the capillary sensory and integrative ability using a micro-pharmacological approach in which micropipettes are filled with either vasoconstrictors or vasodilators. Similarly, Riemann *et al.* (2010) have tried localizing tissue PO<sub>2</sub> perturbations using micropipettes to deliver liquids with low O<sub>2</sub>. However, the study was conducted without measuring the impact on tissue O<sub>2</sub> levels or erythrocyte SO<sub>2</sub>, which is critical to establish that an SO<sub>2</sub>-dependent signal is induced (Jackson and Duling 1983). Until now, no technique has been developed that allows for altering and measuring erythrocyte SO<sub>2</sub> in selected capillaries and to simultaneously record corresponding micro-vascular hemodynamic responses.

## **1.6 Computational modeling of erythrocyte SO<sub>2</sub>-dependent ATP signaling**

The O<sub>2</sub> regulatory system in the microcirculation involves a number of integrated signaling processes that harmoniously maintain homogenous O<sub>2</sub> supply in response to the heterogeneity in O<sub>2</sub> demand. The inherent complexities of this system and the lack of current techniques to quantify the release of signaling molecules in response to hypoxia *in vivo* led to the development of theoretical and computational models to investigate micro-vascular O<sub>2</sub> regulation.

A theoretical model presented by Arciero *et al.* (2008) simulated steady-state ATP release in response to variation in O<sub>2</sub> consumption rates along seven representative micro-vessel segments. It was concluded that high O<sub>2</sub> demand stimulates ATP release from

erythrocytes resulting in conducted vasodilation in resistance vessels and concurrent increase in perfusion. It also indicated that metabolic control overrides shear stress or myogenic control mechanisms in terms of flow regulation.

In 2010, Sprague's group, together with Ellis and Goldman (Sprague et al. 2010), presented a computational model showing that mis-regulation of O<sub>2</sub> supply observed clinically, such as in patients with Type-2 Diabetes, cannot be corrected by regional vasodilation. Regional vasodilation results in uniform increase in flow across all downstream microvascular units rather than directing the flow specifically to undersupplied micro-vascular units. Strong vasodilators would be needed to improve oxygenation of undersupplied capillaries. It was concluded that a local sensory and regulatory mechanism is required to retrieve normal O<sub>2</sub> regulation.

Most recently, Goldman et al. 2012 described a novel multiscale modeling approach to investigate O<sub>2</sub>-dependent ATP release and signaling in microcirculation. The model has two components and is based on experimental work. The first component describes ATP release by the erythrocyte through the signaling pathway previously elucidated (Sprague et al. 2001; 2002; 2006, Olearczyk et al 2004a/b, Sridharan, et al. 2010a/b). The second component describes capillary network ATP transport based on realistic *in vivo* measurements of blood flow, O<sub>2</sub> transport, and 3D capillary geometry. The time scales for ATP release calculated in this work were consistent with those calculated experimentally (Dietrich et al. 2000, Wan et al. 2008). This approach was most comprehensive as it allows for simulating dynamic changes in ATP release and for predicting how defects in the signaling pathway may affect O<sub>2</sub> regulation.

## 1.7 Microfluidic technology

Since microfluidic technology emerged ~40 years ago, it has been undergoing rapid development (Gravesen et al. 1993). Microfluidics refers to the “research discipline dealing with transport phenomena and fluid-based devices at microscopic length scales” (Nguyen and Wereley, 2002). Structures at the micro scale, such as outlets or channels, can be patterned in different types of materials using a variety of micro-fabrication techniques for the purpose of transporting or manipulating fluids (Nguyen and Wereley, 2002). This interdisciplinary field has a broad range of applications in engineering, chemistry, physics, and biotechnology. Since the length scales in microfluidic systems approach those in molecular processes, microfluidics technology has been an especially attractive tool with high impact in biological research (Stone and Kim 2001). Integrating multiple microfluidic components into one device allows for preparing, mixing, as well as screening samples in a single chip (Mark et al. 2010) (also referred to as lab-on-chip systems). Such systems have revolutionized diagnostic methods, blood separation, pathological testing, proteomics, and genomics (Herold and Rasooly 2009a,b, Mark et al. 2010).

Recently, Wan et al. (2008) studied shear-dependent ATP release from erythrocytes using a microfluidic approach. Erythrocytes in a cocktail of luciferin/luciferase were pumped through a narrowing in a micro-channel. Measurement of the light intensity signal generated by the ATP-luciferase reaction following erythrocyte deformation downstream of the narrowing was used to estimate the timescales involved in ATP release. Currently, similar research is being conducted at Dr. Ellis’ laboratory to investigate the dynamics of

SO<sub>2</sub>-induced ATP released from the erythrocyte. Hence, the use of microfluidic technology is anticipated to provide valuable insights into the timescales and mechanisms involved in the regulation of microvascular blood flow. Also, since microfluidic systems are highly versatile in design and application, they can be used not only in liquid manipulation and analysis but may also serve as an important tool in the limited transport of gaseous substances; for instance, O<sub>2</sub>.

## 1.8 Summary

In summary, a number of theories and hypotheses exist regarding the mechanisms that regulate O<sub>2</sub> transport and erythrocyte distribution in the microcirculation. It is becoming more evident that the regulatory system must allow for local monitoring and sensing of the micro-vascular O<sub>2</sub> environment. A messenger mechanism must also exist for linking the sensory mechanism with the micro-vascular response. Many studies implicate the erythrocyte as actively involved in micro-vascular O<sub>2</sub> regulation. This is mainly due to its ability to release signaling molecules that act to modulate blood flow in response to a drop in internal hemoglobin SO<sub>2</sub>. This indicates that the erythrocyte may act as a mobile sensor and effector, with the ability to sense changes in O<sub>2</sub> environment through hemoglobin saturation changes and to respond by the release of vasodilators in an SO<sub>2</sub> dependent manner. Of interest is the potent vasodilator ATP, shown to be released from the erythrocyte not only in response to hypoxia but also to a number of other stimuli. The site where this release mechanism is most efficient is still under investigation. The long erythrocyte transit times in the capillaries and the short diffusion distance of released

ATP to the endothelium suggest the capillary may be the site for O<sub>2</sub> signaling. Due to the inherent complexities of micro-vascular control mechanisms, computational and theoretical models have been developed to provide quantitative estimates of changes in the magnitude of ATP release from the erythrocyte under low SO<sub>2</sub> conditions. Also, a number of techniques have been developed to investigate micro-vascular signaling *in vivo*, however, until now no such technique exists for studying micro-vascular responses to local changes in SO<sub>2</sub>, for instance in a few selected capillaries.

## **1.9 Thesis rationale and objectives**

### **1.9.1 Rationale**

Various techniques for exchanging O<sub>2</sub> with tissue surface *in vivo* have been implemented for studying micro-vascular responses to O<sub>2</sub> perturbations. However, none of these reported techniques allows for simultaneously altering and measuring erythrocyte SO<sub>2</sub> in selected capillaries. Limiting the area of O<sub>2</sub> exchange is necessary to investigate the site for major ATP release and signaling in the microvasculature.

In order to address these limitations, a novel micro-fluidic system has been developed for controlling O<sub>2</sub> availability to specific regions on the microvascular bed of intact muscle tissue (rat Extensor Digitorum Longus) (Ghonaim et al. 2011). This approach allows for altering erythrocyte SO<sub>2</sub> in selected capillaries in response to imposed local tissue PO<sub>2</sub> changes. Hemodynamic responses can be recorded simultaneously using IVVM. In this system, an ultrathin glass/plastic sheet micro-fabricated with an O<sub>2</sub> micro-outlet replaces the fluorosilicate acrylate membrane in the original gas exchange chamber (Figure 2).

Three O<sub>2</sub> micro-outlet designs were tested: circular micro-outlet (~100 μm in diameter), a square micro-slit (200 μm x 200 μm) or a rectangular micro-slit (1000 μm wide x 200 μm long).

Due to the complexity involved in studying the microvascular O<sub>2</sub> regulatory system, a computational model was developed based on that presented by Goldman et al. (2012) to describe O<sub>2</sub> exchange across the three proposed outlet designs. The generated 3D tissue PO<sub>2</sub> profiles and ATP vessels maps provided insight into the optimal design for an O<sub>2</sub> micro-outlet. The modeling results suggested that optimal micro-outlet dimensions would allow for activating a sufficient number of capillaries to generate large enough magnitude of ATP signal while maintaining the localization of the signal. Also, the possible contribution of nearby arterioles to the ATP signal was verified.

Experimentally, gas mixture with different concentrations of O<sub>2</sub> was delivered through the micro-outlet to the surface of the muscle. O<sub>2</sub> levels were oscillated using computer controlled flow meters and digitized video sequences were processed for changes in capillary hemodynamic parameters and erythrocyte SO<sub>2</sub>. CO<sub>2</sub> levels and temperature were held constant and PO<sub>2</sub> levels were kept above 15 mmHg ensuring that the primary regulatory response are due solely to changes in regulation of the O<sub>2</sub> supply.

### **1.9.2 Hypothesis**

It is hypothesized that capillaries are able to signal upstream arterioles for changes in erythrocyte supply rate in response to changes in capillary erythrocyte SO<sub>2</sub> via SO<sub>2</sub>-dependent signaling by the erythrocyte.

### 1.9.3 Objectives

1. To design a novel O<sub>2</sub> micro-delivery system for altering erythrocyte SO<sub>2</sub> in selected micro-vessels *in vivo* while simultaneously measuring blood flow responses and SO<sub>2</sub> value;
2. To mathematically model spatially limited O<sub>2</sub> delivery to or removal from the capillary bed and the consequent erythrocyte SO<sub>2</sub>-dependent ATP release. To determine an optimal dimensions for the O<sub>2</sub> micro-outlet in our novel system; and
3. To experimentally investigate conducted micro-vascular signaling and response to varying capillary SO<sub>2</sub> *in vivo* using our optimized novel O<sub>2</sub> micro-delivery system.

## Chapter 2

### 2 A micro-delivery approach for studying microvascular responses to localized oxygen delivery<sup>1</sup>

<sup>1</sup> Research article published in *Microcirculation* (2011) 18 (8), 646-654

#### 2.1 Introduction

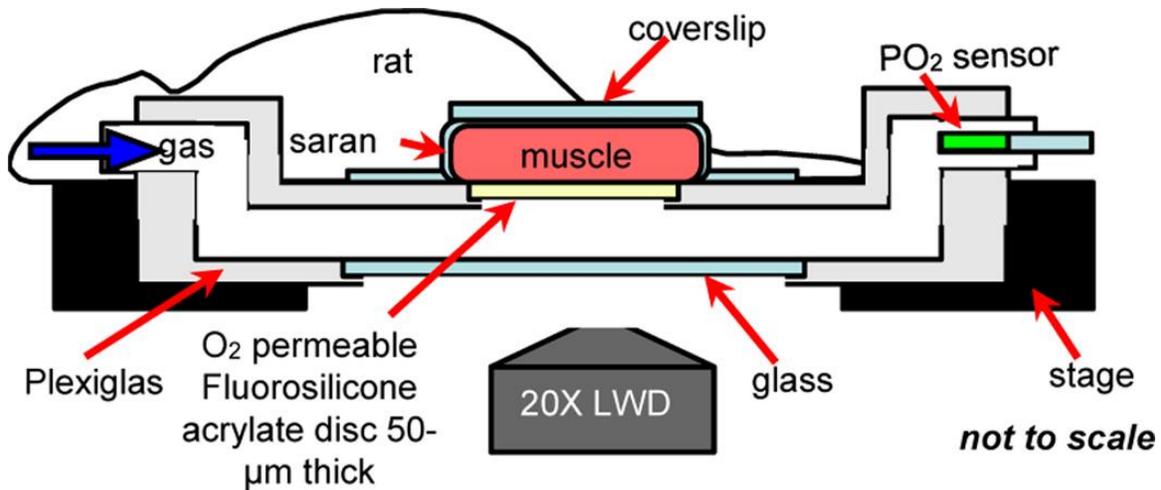

Several medical conditions that are characterized by microvascular dysfunction lead to more critical problems such as tissue hypoxia and organ failure (Ellis et al. 2005). The understanding of the pathophysiology underlying these conditions depends on the understanding of oxygen (O<sub>2</sub>) transport and its regulation under physiological conditions. Previous studies have demonstrated that red blood cells (RBCs) have an O<sub>2</sub>-dependent release of adenosine triphosphate (ATP), which is directly correlated to the oxygen saturation (SO<sub>2</sub>) level of haemoglobin (Ellsworth et al. 1995, 2009, Jagger et al. 2001). Under hypoxic conditions, a signal transduction pathway is modulated in RBCs, which results in increased ATP release and purinergic receptor activation on the vascular endothelium (Ellsworth et al. 2009). In arterioles, this leads to the production of signaling molecules, such as nitric oxide (NO) in the endothelium, that cause local vascular smooth muscle dilation. In addition, activation of P2Y<sub>2</sub> receptors initiates conducted signaling along the vascular endothelium in both arterioles and capillaries resulting in upstream vascular dilation to increase the supply of O<sub>2</sub>-carrying red blood cells (Ellsworth et al. 2009). Type-II diabetes is a medical condition associated with peripheral vascular

dysfunction and impaired tissue oxygenation. Interestingly, it has recently been shown that RBCs from type II diabetes patients suffer defects in the release of ATP (Sprague et al. 2006) and that RBCs from humans and animal models of prediabetes have attenuated release of ATP in response to a decrease in O<sub>2</sub> levels (Hanson et al. 2009, Ellis et al. 2010).

*In vivo* video-microscopy (IVVM) techniques, which allow for monitoring and recording real-time changes in blood flow properties within the microcirculation (Dewhirst et al. 2000, Ellis et al. 2010, Varghese et al. 2005), have been used to study the blood flow characteristics as a function of local O<sub>2</sub> concentration in capillary microcirculatory networks. The classical setup involves altering O<sub>2</sub> partial pressure (PO<sub>2</sub>) levels in the superfusion solution equilibrating the surface of a tissue or a vessel (Duling 1974, Jackson and Duling 1983). However, the use of a superfusion solution may alter the physiological environment by continuously washing away substances from the surface of the tissue and can potentially affect the microvascular response by depleting the tissue of molecules involved in microvascular signalling. Another limitation of using superfusion solution as a medium for O<sub>2</sub> delivery is the relatively low solubility of O<sub>2</sub> in saline solution.

The IVVM setup currently used in our lab involves varying the levels of O<sub>2</sub> transported to the surface of the rat Extensor Digitorum Longus (EDL) muscle using a gas exchange chamber positioned on the viewing platform of an inverted microscope (see Figure 2.1). More specifically, O<sub>2</sub> is delivered through a 4 mm × 10 mm window covered with fluorosilicone acrylate O<sub>2</sub> permeable membrane of 50 µm thickness. The tissue is trans-illuminated and real-time videos of blood flow changes in the microcirculation are

recorded while simultaneously controlling local O<sub>2</sub> levels in the chamber using computer-controlled flow meters. Direct O<sub>2</sub> delivery through a highly O<sub>2</sub> permeable membrane such as fluorosilicone acrylate (O<sub>2</sub> permeability coefficient = 100 Barrers, where 1 Barrer = 10<sup>-11</sup> (cm<sup>3</sup> O<sub>2</sub> STP) cm<sup>2</sup> cm<sup>-3</sup> sec<sup>-1</sup> mmHg<sup>-1</sup> (Comyn 1985)) has a greater effect on tissue PO<sub>2</sub> levels than when using liquid media. Also, this setup offers minimal disturbance to the tissue's physiological environment. However, the dimensions of the O<sub>2</sub> delivery window are proportional to the *in situ* dimensions of the EDL muscle. Hence, the current IVVM setup measures the collective response of stimulating a very large area of the microvascular network at the muscle surface (Figure 2.1). Riemann *et al.* (2010) have recently tried to limit the area affected by O<sub>2</sub> using micropipettes for infusing liquids with low O<sub>2</sub> but without measurement of the impact on tissue O<sub>2</sub> levels or RBC saturation. The ability to measure RBC SO<sub>2</sub> is critical to establish that an SO<sub>2</sub> dependent microvascular signal is induced (Jackson and Duling 1983).

**Figure 2.1** Classical IVVM experimental setup. Extensor Digitorum Longus (EDL) muscle of the rat is surgically exposed and positioned surface down on the viewing platform of an inverted light microscope. O<sub>2</sub> is delivered to the muscle using a gas exchange chamber connected to computer-controlled flow meters. O<sub>2</sub> levels in the chamber are measured and monitored using a fibre optic O<sub>2</sub> sensor probe. The tissue is trans-illuminated and blood flow responses are recorded and analyzed as O<sub>2</sub> levels are simultaneously oscillated.

In this study, a micro-delivery approach was developed for investigating localized microvascular signaling and response to varying tissue PO<sub>2</sub> levels. We have limited the area of O<sub>2</sub> perturbation at the microvascular bed within live muscle tissue (rat EDL) by 40 fold relative to the original gas exchange chamber setup. Gas with varying levels of O<sub>2</sub> was directly transported to the surface of the EDL muscle through a set of micro-outlets (~100 µm in diameter) patterned in an ultrathin glass sheet using state-of-the-art microfabrication techniques. RBC SO<sub>2</sub> changes due to O<sub>2</sub> level oscillations were measured and recorded while simultaneously controlling local O<sub>2</sub> levels. This novel

approach aims to provide greater insight into the underlying mechanisms of microvascular control.

## 2.2 Materials and Methods

### 2.2.1 Mathematical modeling of the PO<sub>2</sub> distribution profile

The oxygen partial pressure (PO<sub>2</sub>) distribution profile through an O<sub>2</sub> delivery micro-outlet interfaced directly with live tissue was modeled using an O<sub>2</sub> transport code written in MATLAB (Mathworks, Natick, MA). The model simulates O<sub>2</sub> diffusing through varying sized outlets (20 μm, 50 μm, 100 μm, and 200 μm in diameter) patterned in a zero thickness material into tissue that consumes O<sub>2</sub> and also has a continuous distribution of capillary O<sub>2</sub> sources. We have shown previously that O<sub>2</sub> transport through tissue of this type differs from O<sub>2</sub> transport through a purely diffusive medium (Goldman 2008). In the present case, a finite-difference method is used to solve the axisymmetric 3-D problem of axial and radial diffusion, for instance, from a 100 μm outlet ( $x=0, r \leq 50 \mu\text{m}$ ) into the overlying tissue ( $0 < x \leq 500 \mu\text{m}, 0 \mu\text{m} < r \leq 500 \mu\text{m}$ ) with no-flux boundary conditions at  $r=500 \mu\text{m}, x=500 \mu\text{m}$  and  $x=0$  for  $r > 50 \mu\text{m}$ . The micro-outlet PO<sub>2</sub> was set to be 205 mmHg (27% O<sub>2</sub>) and the far-field tissue PO<sub>2</sub> ( $P_\infty$ ) was set to be 42 mmHg (typical tissue PO<sub>2</sub> under normal resting conditions). As described in Goldman (2008), the other parameters needed for the O<sub>2</sub> transport model were the tissue O<sub>2</sub> diffusion coefficient ( $D=2.41 \times 10^{-5} \text{cm}^2/\text{s}$ ), O<sub>2</sub> solubility ( $\alpha=3.89 \times 10^{-5} \text{ml O}_2/\text{ml/mmHg}$ ), O<sub>2</sub> consumption rate ( $M_0=1.5 \cdot 10^{-4} \text{ml O}_2/\text{ml/s}$ ), and the mean capillary PO<sub>2</sub> ( $P^*=48 \text{mmHg}$ ). Note that  $P_\infty$  and

$P^*$  represent, respectively, average tissue and capillary values far from the outlet, and hence should not be affected by the outlet  $PO_2$ .

### **2.2.2 Microfabrication**

Oxygen delivery micro-outlets with a diameter of  $\sim 100 \mu\text{m}$  and a pitch of  $\sim 277 \mu\text{m}$  (center-to-center) were patterned in  $30 \mu\text{m}$  thick D263C borosilicate glass substrate (SCHOTT North America) by photolithography and subsequent wet etching in hydrogen fluoride. The photolithography and wet etching steps were carried out similar to previously described procedures (Ilie et al. 2003, Srivastava et al. 2005). Since the etching is isotropic, there is a certain degree of undercutting beneath the masking layers (Ilie et al. 2003). This results in the pattern to be larger on the glass relative to the photomask. Also, due to the undercutting, the micro-outlet would be cone-shaped rather than cylindrically shaped, which means that the diameter is larger right beneath the masking layer. All pattern dimensions were optically measured at the top glass surface (glass surface directly beneath the masking layers) using QCapture Pro™ 6.0 software. The patterned ultrathin glass substrate replaced the  $O_2$  permeable fluorosilicone acrylate in the original IVVM setup (Figure 2.1).

### **2.2.3 *In vivo* video microscopy**

RBC  $SO_2$  levels in response to  $O_2$  delivery through the micro-outlets were measured using IVVM techniques. These measurements were used to assess the tissue response time for  $O_2$  delivery from the micro-outlets as well as to validate the model results.

### **2.2.3.1 Animal preparation**

All procedures described are approved from the University of Western Ontario's Animal Care and Use Committee. Male Sprague-Dawley rats (Charles River Laboratories, Wilmington, MA) (150–200 g) were anesthetized with pentobarbital sodium (6.5 mg/100 g body wt IP) and were subjected to a preparatory surgery as described (Ellis et al. 2002, 2010). The animals were mechanically ventilated at 30% O<sub>2</sub> (70% Nitrogen), and the inspired O<sub>2</sub> level (Oxychek) and blood pressure (MicroMed) were constantly monitored and recorded (Ellis et al. 2010). The Extensor Digitorum Longus (EDL) muscle of the hind limb was identified and prepared for *in vivo* video microscopy as described by Tysl and Budreau (1991). The muscle was extended along the viewing platform of a Nikon inverted microscope equipped with long-working distance 10X and 20X objectives and a beam splitter for dual video cameras (DAGE-MTI CCD cameras). A suture attached to the edge of the muscle was taped to the platform. The muscle was covered with Saran Wrap (Dow Corning) and a cover slip to isolate it from room air and to preserve moisture. The tissue was trans-illuminated with a 100-W xenon lamp and viewed using the dual video camera system as previously described (Ellis et al. 2010).

### **2.2.3.2 Dual video camera intravital microscopy system**

Real-time video recordings (640 × 480, 30 frames/second) of RBC flow through capillaries were simultaneously obtained at two wavelengths, 431 nm, an O<sub>2</sub> sensitive wavelength for hemoglobin, and 420 nm, an isosbestic or O<sub>2</sub> insensitive wavelength (Ellsworth et al. 1987) using the dual video camera intravital microscopy system (Ellis et al. 2010). Live video sequences were digitized and stored as uncompressed AVI movie

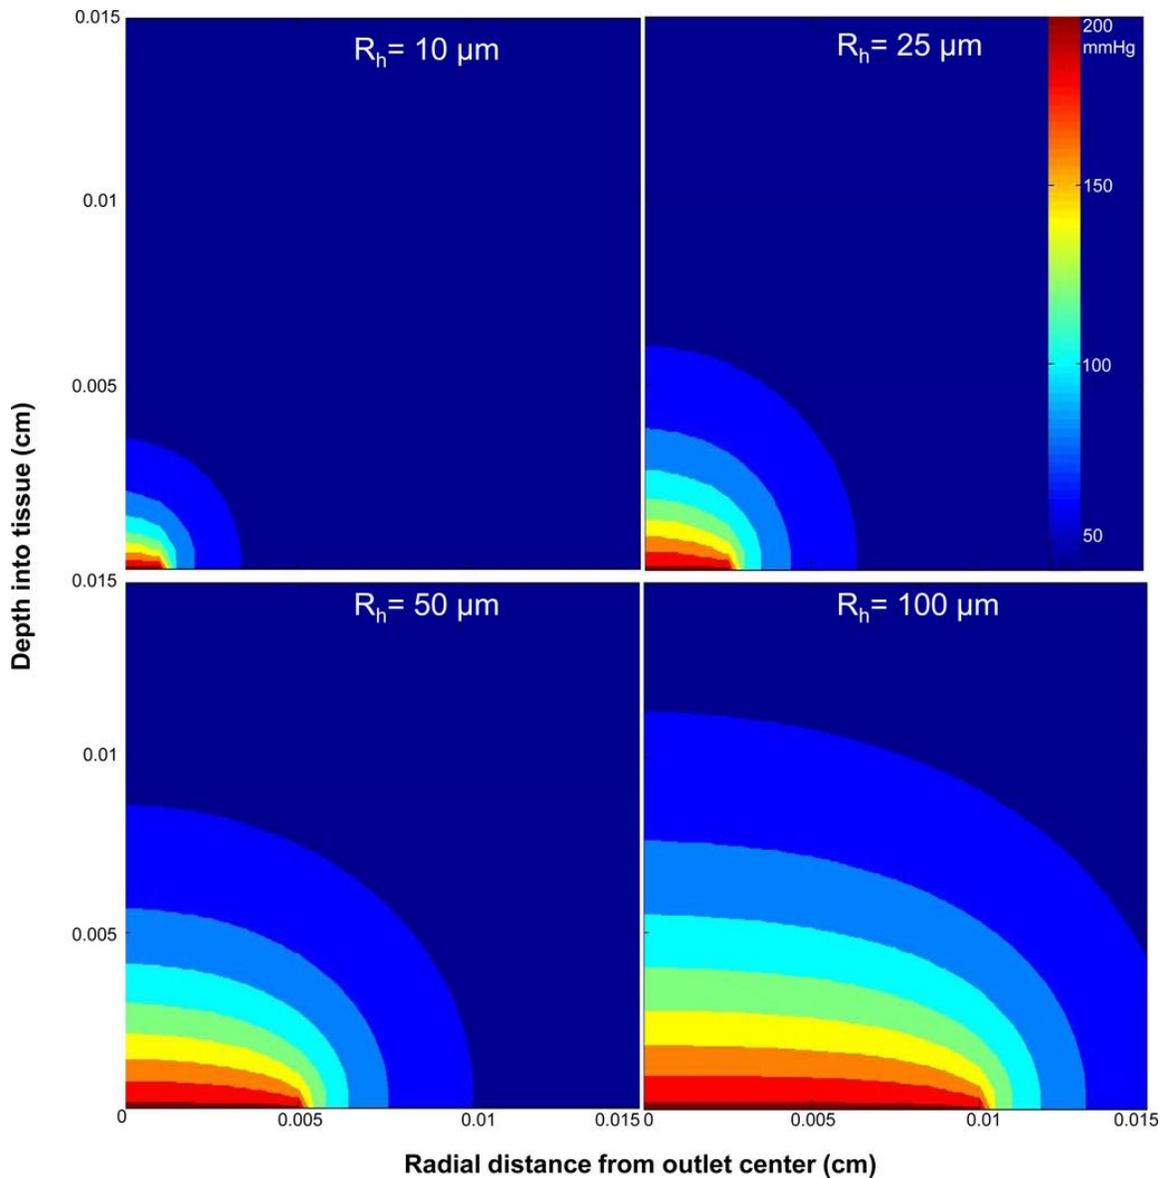

files using custom acquisition software from Neovision (Ellis et al. 2010) for post-processing. Geometric, spatiotemporal, and photometric off-line analyses of the AVI files (for both 420 nm and 431 nm wavelengths) were conducted as described by Ellis et al. (Ellis et al.. 1990, 1992) and Japee et al. (Japee et al. 2004, 2005) using algorithms written in MATLAB (Mathworks, Natick, MA) to quantify changes in capillary hemodynamic parameters and erythrocyte  $SO_2$ . Parameters measured include average RBC velocity, supply rate, lineal density, and RBC  $SO_2$ (Ellis et al.. 1990, 1992, Japee et al. 2004, 2005).

## **2.3 Results**

### **2.3.1 Mathematical modeling of the $PO_2$ distribution profile**

Microvascular responses to variations of local tissue  $PO_2$  levels were examined by delivering or removing  $O_2$  at specific locations on the surface of the rat EDL muscle through a set of micro-outlets patterned in ultrathin glass. Prior to the microfabrication step (see Materials and Methods), the desired micro-outlet diameter was estimated by computational modeling in MATLAB (Mathworks, Natick, MA). The criteria guiding the modeling and final selection of micro-outlet geometry were determined by the maximum depth a capillary can be into the tissue for accurate analysis with our current microscopy techniques (50–60  $\mu m$ ) and the average dimensions of a microvascular unit (150  $\mu m \times$  400  $\mu m$ ). Also, the separation between adjacent micro-outlets must be great enough for the  $PO_2$  stimuli from each to be independent. Thus, in the simulation, the micro-outlet diameter was selected based on the depth of  $O_2$  penetration into the tissue and the degree of radial diffusion away from the center of the outlet. Optimal micro-outlet dimensions

would allow for limiting the amount of radial diffusion of O<sub>2</sub> away from the center of an outlet, which maximizes the amplitude of O<sub>2</sub> diffusion into the tissue. The PO<sub>2</sub> distribution model for micro-outlets of 20 μm, 50 μm, 100 μm, and 200 μm in diameter (see Materials and Methods) showed an increase in the depth of penetration with increasing micro-outlet diameter; however, the degree of radial diffusion was unaffected by the size of the micro-outlet (Figure 2.2). The simulation suggested a limited amount of radial diffusion extending to about 25% of the micro-outlet diameter. The model indicated that below a 100 μm outlet diameter, the depth of PO<sub>2</sub> transport into the tissue is too small to ensure that capillary oxygenation will be affected. Above 100 μm, the depth of PO<sub>2</sub> transport increases; yet accompanied by a concurrent increase in the area of the tissue influenced by local PO<sub>2</sub> changes. For a 100 μm diameter outlet, we could affect an area ~150 μm in diameter with a depth of penetration of ~55 μm per outlet (Figure 2.2). Thus, a 100 μm micro-outlet was chosen as the minimum desired size since it would allow for altering the O<sub>2</sub> level of a specific region within a microvascular unit to the depth of our ability to analyze. The original O<sub>2</sub> delivery system was modeled as 1D diffusion resulting in the depth of penetration of ~100 μm (Goldman 2008). With the micro-outlets, the diffusion is physically 3D (mathematically 2D due to axisymmetry) and as expected the depth of penetration is less.

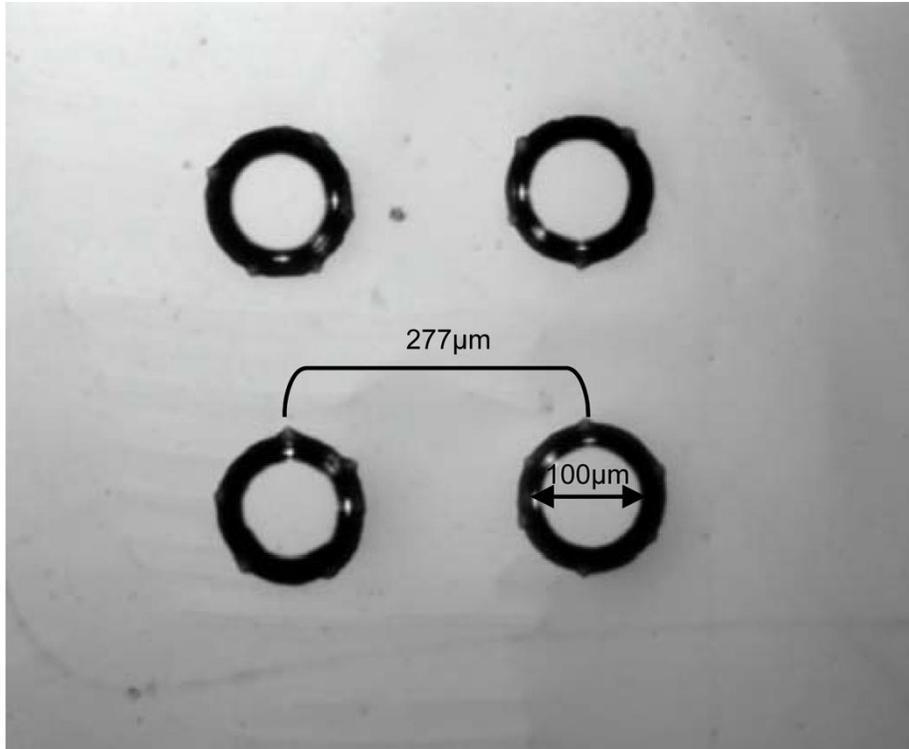

**Figure 2.2** Calculated  $PO_2$  distribution for  $O_2$  delivery into live metabolic tissue through micro-outlets of various sizes ( $10\ \mu\text{m}$ ,  $25\ \mu\text{m}$ ,  $50\ \mu\text{m}$ , and  $100\ \mu\text{m}$  in radius ( $R_h$ )). Using  $P_{norm}(r,x) = (P(r,x) - P_\infty) / (P_{outlet} - P_\infty)$  and a cut-off of  $P_{norm} = 0.25$ , the radius of lateral  $O_2$  diffusion from the center of the micro-outlet is constant at  $\sim 150\%$  of the radius while the depth of penetration increases with increasing outlet radius. The width of the tissue in this model ( $R_t$ ) was set to  $500\ \mu\text{m}$ , however, the maximum value on the x-axis in the  $PO_2$

distribution plots was set to 150  $\mu\text{m}$  for clarity. Computational modelling was conducted using algorithms written in MATLAB (Mathworks, Natick, MA).

### **2.3.2 Microfabrication**

Oxygen delivery micro-outlets were patterned in ultrathin D263T borosilicate glass substrate (SCHOTT North America) based on the mathematical  $\text{PO}_2$  distribution model described before. To test microvascular responses at different areas on the surface of the EDL muscle, multiple micro-outlets were patterned in ultrathin glass with a diameter of  $\sim 100 \mu\text{m}$  separated by  $\sim 277 \mu\text{m}$  center-to-center distance (Figure 2.3). The area simultaneously examined could be within a single microvascular network unit ( $\sim 150 \mu\text{m} \times 400 \mu\text{m}$ ) or could be located at adjacent units.

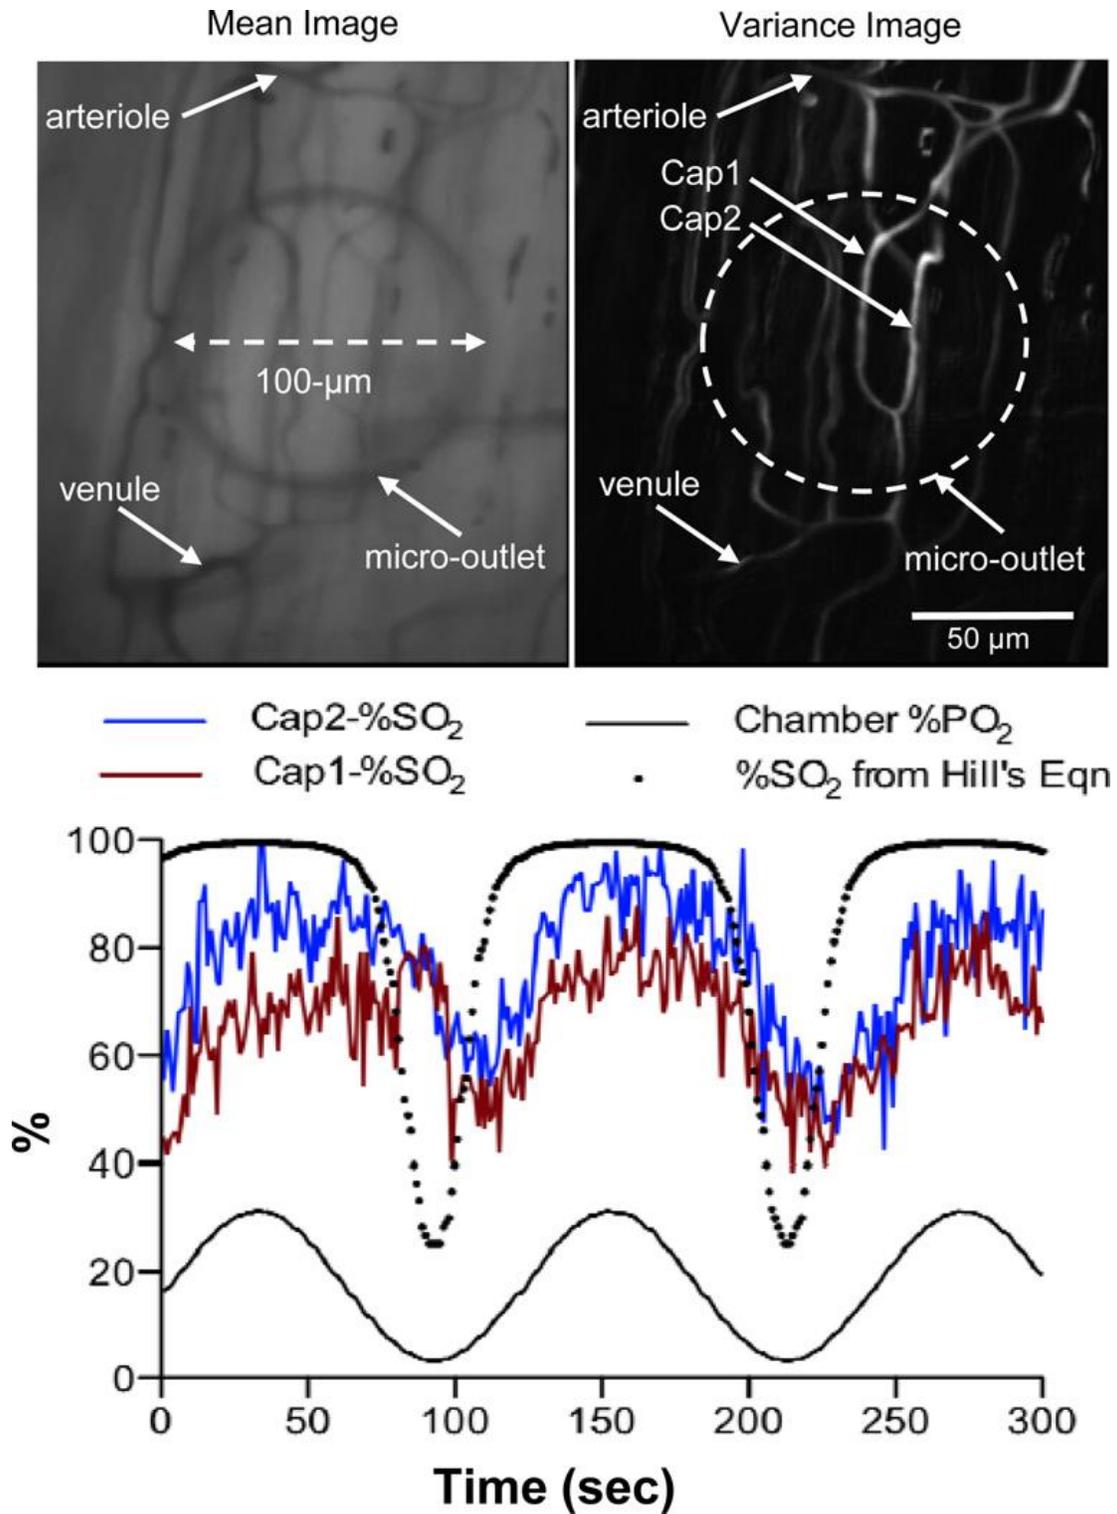

**Figure 2.3** Oxygen delivery micro-outlets  $\sim 100 \mu\text{m}$  in diameter separated by  $\sim 277 \mu\text{m}$  distance (center-to center) patterned in D263T borosilicate ultrathin glass substrate as they appear under an upright light microscope at 10x objective. The micro-outlets were microfabricated using photolithography and subsequent wet etching in hydrogen fluoride.

### **2.3.3 Micro-delivery system *in vivo* validation**

Prior to *in vivo* analysis,  $\text{O}_2$  delivery through the designed micro-outlets was verified *in vitro* using the NeoFox® Phase Measurement System ( $\text{O}_2$  sensing cover slip, FOXY sensor formulation, Ocean Optics, Inc.). Parameters examined included the  $\text{PO}_2$  level changes associated with the micro-outlets and the response time. Following the *in vitro* validation, the effects of  $\text{O}_2$  delivery through the micro-outlets were tested on live tissue (rat EDL muscle) using IVVM (see Materials and Methods).

### **2.3.3.1 Sine wave oscillations**

With the aid of an inverted microscope, selected capillaries, designated as Cap1 and Cap2, on the surface of the EDL muscle were positioned on top of an O<sub>2</sub> delivery micro-outlet (Figure 2.4). The edge of the micro-outlet could be clearly viewed when focussing away from the tissue at 20X objective (Figure 2.4). The PO<sub>2</sub> level in the chamber was oscillated in a sine wave pattern (period 120 seconds) and a six minute video sequence was captured to examine RBC SO<sub>2</sub> changes within the selected capillaries. Analysis of the postprocessed video sequence shows a close association between the oscillated chamber PO<sub>2</sub> levels and the RBC SO<sub>2</sub> changes in both Cap1 and Cap2 with a lag time of approximately 10 seconds (Figure 2.4). The shape of the SO<sub>2</sub> time series is flattened at high O<sub>2</sub> saturations and steeper at low O<sub>2</sub> saturations, which is consistent with the sigmoidal shape of the hemoglobin O<sub>2</sub> saturation curve (Hill 1910). This was further confirmed by comparing the measured RBC SO<sub>2</sub> time series to the SO<sub>2</sub> curve calculated using Hill's equation and the measured chamber PO<sub>2</sub> values (Figure 2.4) (Hill 1910). As expected, the range of SO<sub>2</sub> values are greater in the calculated SO<sub>2</sub> curve and the lag time is absent when compared to the measured SO<sub>2</sub> data (Figure 2.4). Analysis of hemodynamic data indicated that the mean supply rate in Cap1 was higher ( $\sim 13.2 \pm 5.2$  cells/sec, N=360) than in Cap2 ( $\sim 4.3 \pm 3.2$  cells/sec, N=360).

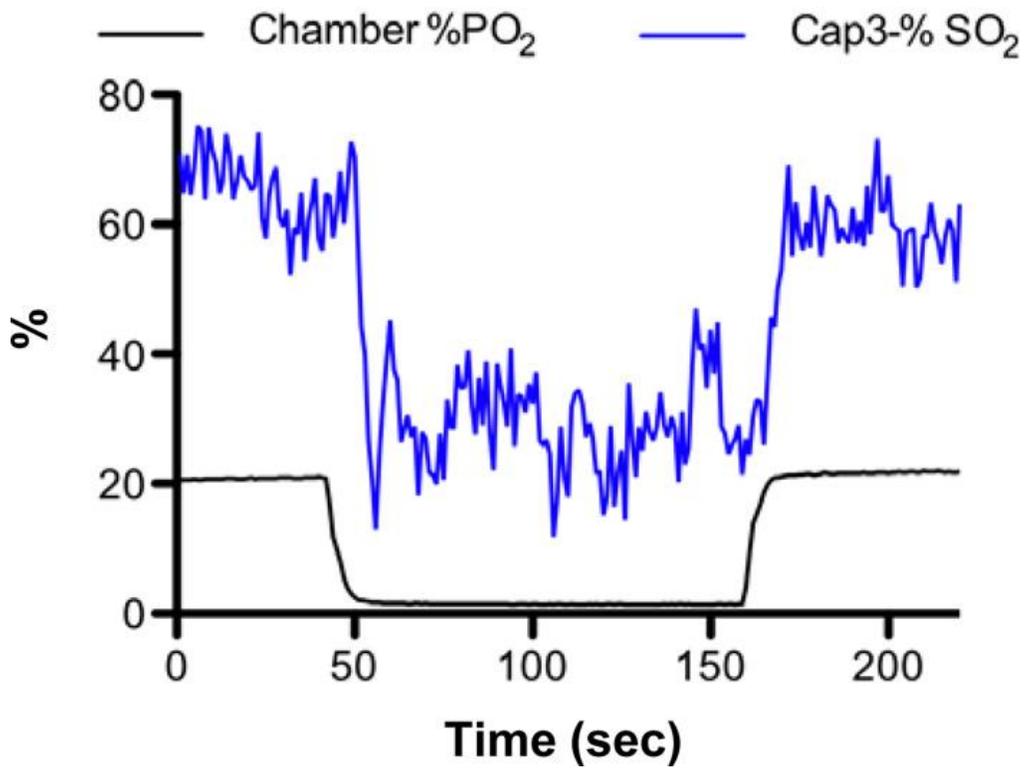

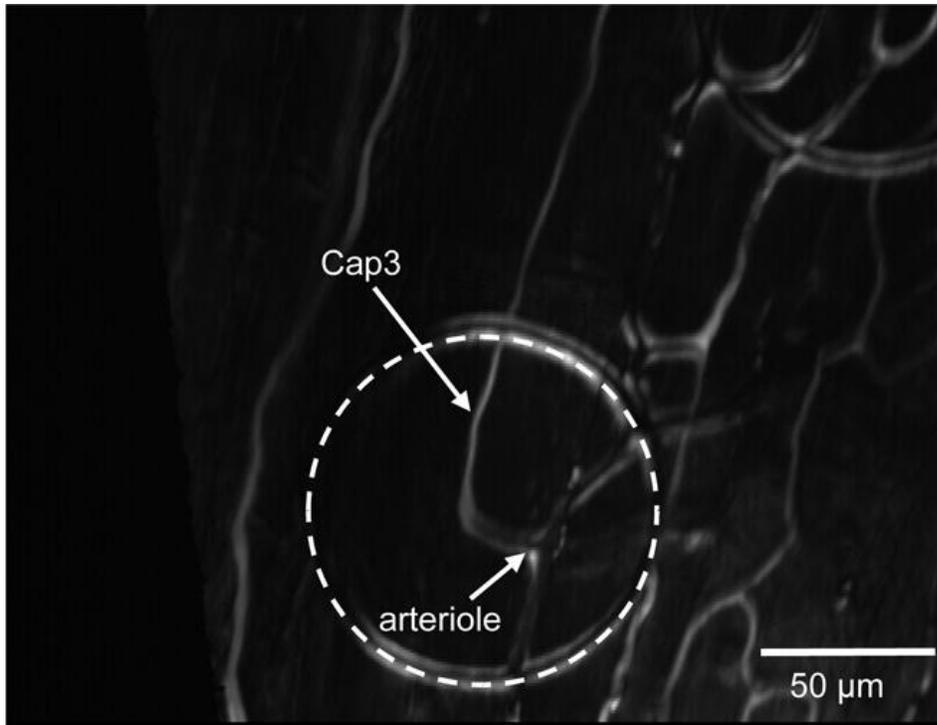

**Figure 2.4** Muscle preparation with transparent micro-outlets positioned under the muscle. The edge of the micro-outlet is clearly visible in the 20X Mean Image showing

the outlet positioned under the capillary network between the arteriole and venule. In focus capillaries for analysis are visible in the Variance Image of the same field of view. Selected capillaries Cap1 and Cap2 were analyzed for RBC SO<sub>2</sub> changes as O<sub>2</sub> levels delivered through the micro-outlet were oscillated in a sine wave (of 120 second period). Videos of the selected region were simultaneously recorded at both 431 nm and 420 nm wavelengths using the dual video camera intravital microscopy system. The video sequences were digitized and postprocessed off-line using algorithms written in MATLAB to quantify changes in the RBC SO<sub>2</sub>. The RBC SO<sub>2</sub> profiles of both capillaries are closely associated with the local O<sub>2</sub> oscillations. The shape of the SO<sub>2</sub> profiles for the selected capillaries also follows that of the SO<sub>2</sub> curve calculated using the Hill's equations and the measured chamber PO<sub>2</sub> values. The difference in the measured baseline SO<sub>2</sub> values between Cap 1 and Cap2 is likely due to the difference in their mean supply rates with Cap1 having higher supply rate ( $\sim 13.2 \pm 5.2$  cells/sec, N=360) than Cap2 ( $\sim 4.3 \pm 3.2$  cells/sec, N=360).

### **2.3.3.2 Square wave oscillations**

A selected capillary, designated as Cap3, on the surface of the EDL muscle was positioned on top of a micro-outlet (Figure 2.5). The PO<sub>2</sub> level in the chamber was decreased from 22% ( $\sim 167$  mmHg) to 1.4% ( $\sim 10.6$  mmHg) for a 120 second hypoxic challenge and back to 22%. A video sequence was recorded over a six minute period beginning 2 minutes before the hypoxic challenge. The video was postprocessed for changes in capillary hemodynamic parameters and erythrocyte SO<sub>2</sub>. Similar to our observations with induced sine oscillations of tissue PO<sub>2</sub> levels (Figure 2.4), RBC SO<sub>2</sub>

changes were closely associated with the chamber PO<sub>2</sub> level with a lag time of approximately 7 seconds (Figure 2.5). The mean supply rate for Cap3 was measured to be  $\sim 9.4 \pm 3.4$  cells/sec, N=220.

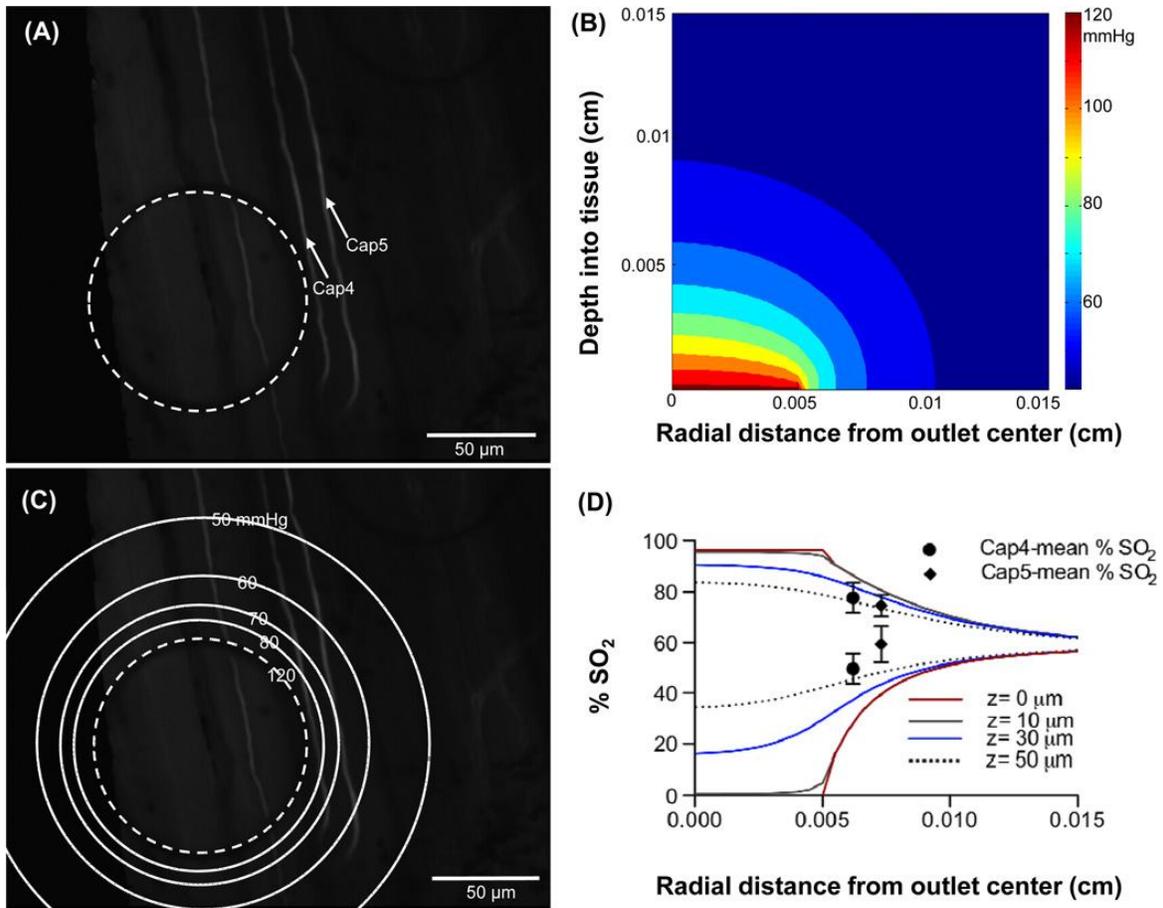

**Figure 2.5** Selected capillary Cap3 was analyzed for RBC SO<sub>2</sub> changes as O<sub>2</sub> levels delivered through the micro-outlet were oscillated in a square wave. The PO<sub>2</sub> level in the

chamber was decreased from 22% (~167 mmHg) to 1.4% (~10.6 mmHg) for a 120 second hypoxic challenge and back to 22%. A six minute video sequence was captured beginning 2 minutes before the hypoxic challenge. The RBC  $SO_2$  profile is closely associated with the chamber  $PO_2$  level. The mean supply rate for Cap3 was measured to be  $\sim 9.4 \pm 3.4$  cells/sec, N=220.

### **2.3.4 *In vivo* examination of radial diffusion**

Following *in vivo* validation of  $O_2$  delivery through the micro-outlets, the extent of radial diffusion from the center of the micro-outlet was examined *in vivo*. Selected capillaries, designated as Cap4 and Cap5, were positioned adjacent to a micro-outlet with the aid of the inverted microscope (Figure 2.6, panel A). The average distance of the selected capillaries from the center of the micro-outlet were calculated to be 62.2  $\mu m$  and 73.2  $\mu m$ , respectively. The  $PO_2$  level in the chamber was decreased from 16.2% (~123 mmHg) to 0.2% (~1.5 mmHg) for a 120 second hypoxic challenge and back to 16.2%. A video sequence was recorded over a six minute period beginning 2 minutes before the hypoxic challenge. The video was postprocessed for changes in hemodynamic parameters and capillary erythrocyte  $SO_2$ . The mean  $SO_2$  was calculated over a 40 second period prior to inducing local hypoxia (t=50–90 seconds) and over a 40 second period during the hypoxic challenge (t=160–200 seconds) for both Cap4 and Cap5. The difference in the means was calculated to be 28.0% for Cap4 and 15.1% for Cap5. The tissue  $PO_2$  distribution profile was modelled (Figure 2.6, panel B) and the surface (depth=0 cm)  $PO_2$  contour lines were superimposed on top of the image showing the micro-outlet and the selected capillaries (Figure 2,6, panel C). The RBC  $SO_2$  at various depths into the tissue

( $z=0 \mu\text{m}$ ,  $10 \mu\text{m}$ ,  $30 \mu\text{m}$ , and  $50 \mu\text{m}$ ) were calculated from the  $\text{PO}_2$  values predicted by the model using Hill's equation (Hill 1910). The calculated  $\text{SO}_2$  values were then plotted against the radial distance from the center of the micro-outlet (Figure 2.6, panel D). The  $\text{SO}_2$  plots calculated based on the  $\text{PO}_2$  distribution model into the tissue at baseline ( $\text{SO}_2$  decreasing with radial position) or during hypoxia ( $\text{SO}_2$  increasing with radial position) all converge to a value of 60% which corresponds to the tissue  $\text{PO}_2$  level set in the model ( $\sim 42 \text{ mmHg}$ ). Experimentally measured  $\text{SO}_2$  mean values for Cap4 and Cap5 at baseline and during hypoxia were plotted and compared with the predicted  $\text{SO}_2$  against the capillaries' measured distance from the center of the micro-outlet (Figure 2.6, panel D). The maximum mean  $\text{SO}_2$  values for both Cap 4 and Cap5 fall between the model predicted  $\text{SO}_2$  plots for  $30 \mu\text{m}$  and  $50 \mu\text{m}$  depth into the tissue. However, the minimum mean  $\text{SO}_2$  values for both Cap 4 and Cap5 lay above the  $\text{SO}_2$  values predicted for  $50 \mu\text{m}$  depth into the tissue.

**Figure 2.6** Selected capillaries Cap4 and Cap5 shown in panel A were analyzed for RBC SO<sub>2</sub> changes as O<sub>2</sub> levels delivered through the micro-outlet were oscillated in a square wave. The PO<sub>2</sub> level in the chamber was decreased from 16.2% (~123 mmHg) to 0.2% (~1.5 mmHg) for a 120 second hypoxic challenge and back to 16.2%. A six minute video sequence was captured beginning 2 minutes before the hypoxic challenge. The PO<sub>2</sub> distribution profile into the tissue was modelled. Panel B shows a 2D contour plot for a micro-outlet PO<sub>2</sub> value of 123 mmHg. Panel C shows the surface (depth=0 cm) PO<sub>2</sub> contour lines superimposed on top of the image showing the micro-outlet and the selected capillaries. The radial change in RBC SO<sub>2</sub> at various depths into the tissue (z=0  $\mu\text{m}$ , 10  $\mu\text{m}$ , 30  $\mu\text{m}$ , and 50  $\mu\text{m}$ ) were calculated from the modelled PO<sub>2</sub> values using Hill's

equation then plotted against the radial distance from the center of the micro-outlet for a micro-outlet  $PO_2$  values of 123 mmHg (upper set of lines, panel D) and 1.5 mmHg (lower set of lines, panel D). Experimentally calculated  $SO_2$  mean values for Cap4 and Cap5 prior to and during hypoxia were plotted versus capillary location (upper and lower pair of symbols respectively, panel D).

## 2.4 Discussion

The aim of this research was to develop a micro-delivery approach for investigating localized microvascular signalling and response to varying  $PO_2$  levels in live tissue. This was accomplished by designing  $O_2$  delivery micro-outlets in ultrathin glass using microfabrication techniques. The proposed dimensions of the patterned micro-outlets were estimated by mathematically modelling the  $PO_2$  distribution profile for micro-outlets of varying sizes in live tissue using a numerical simulation code written in MATLAB (Figure 2.2) (Mathworks, Natick, MA).  $O_2$  delivered to the microcirculation alters the  $SO_2$  levels of RBCs but is also partly consumed by the surrounding metabolic tissue. The microcirculation system constantly fine tunes the local hemodynamic and geometrical properties in response to changes in the RBC  $SO_2$  levels (Ellis et al. 2005, Ellsworth et al. 2009). This is the mechanism by which the microvasculature matches  $O_2$  supply into the tissue with the metabolic demand. Just like any stimulus-response mechanism, the system is sensitive to a specific threshold of applied stimulus. Hence, an optimal outlet diameter should deliver enough  $O_2$  into the tissue to stimulate a microvascular response. Yet, this should not compromise the accurate localization of the stimulus. In other words, radial diffusion away from the center of the micro-outlet must

be limited to create enough contrast between the area stimulated and nearby regions of the microvascular bed. Also, when choosing the dimensions of the O<sub>2</sub> delivery micro-outlet, the microvascular geometry, specifically the dimensions of a single microvascular unit must be considered. The size of a microvascular unit within the rat skeletal muscle is approximately 150 μm × 400 μm. To better understand the microvascular response mechanism, the size of the micro-outlet must allow us to examine specific locations within a single microvascular unit. For instance, it would be insightful to investigate the effects of inducing local hypoxia at the venular end as opposed to the arteriolar end, or to examine the effects of stimulating a single or multiple capillaries. Hence, a proposed micro-outlet diameter of ~100 μm was selected based on the computational model and the above considerations. Note that the computational model assumes a continuous distribution of capillaries throughout the tissue region of interest. Since this is an approximation whose accuracy will depend on local properties (e.g., capillary spacing and whether or not the micro-outlet directly overlays surface capillaries), the predictions of the model need to be validated by experimental observations.

The O<sub>2</sub> permeable fluorosilicone acrylate membrane in the original IVVM setup was replaced by the ultrathin glass substrate patterned with the O<sub>2</sub> delivery micro-outlets (Figure 2.1). O<sub>2</sub> levels transported through the outlets could be oscillated using computer controlled flow meters connected to the gas exchange chamber. Therefore, it was essential to validate the relationship between the chamber PO<sub>2</sub> oscillations and those delivered through the micro-outlets. This was done *in vivo* by testing the response to O<sub>2</sub> delivery through the micro-outlets to interfaced live tissue (rat EDL muscle) using IVVM. The RBC SO<sub>2</sub> levels altered in response to oscillating the tissue PO<sub>2</sub> levels using

the micro-outlets for O<sub>2</sub> delivery. The RBC SO<sub>2</sub> changes were closely associated with the oscillated chamber PO<sub>2</sub> levels during both sine wave and square wave oscillations, however, with a certain time lag in both cases (Figure 2.4 and Figure 2.5). It is critical to note the absence of such a response delay between sensed and chamber PO<sub>2</sub> levels when testing for O<sub>2</sub> delivery through the micro-outlets *in vitro* (data not shown). Hence, the time lag observed between the measured RBC SO<sub>2</sub>s (essentially sensed PO<sub>2</sub>) and the chamber PO<sub>2</sub> oscillations *in vivo* cannot be attributed to a systematic error. Rather, the delay in tissue response is probably due to O<sub>2</sub> diffusion through the tissue to the RBCs.

For the sine wave oscillation data, similar to the measured RBC SO<sub>2</sub> profile, the SO<sub>2</sub> curve estimated from the measured chamber PO<sub>2</sub> data using Hill's equation (Hill 1910) shows a rapid change at lower PO<sub>2</sub> levels and plateaus as the PO<sub>2</sub> reaches peak levels (Figure 2.4). This typical relationship between PO<sub>2</sub> and RBC SO<sub>2</sub> is due to the cooperative binding of hemoglobin to O<sub>2</sub> (Hill 1910). The difference observed between the estimated and measured SO<sub>2</sub> minima indicates that the RBCs in the selected capillaries were experiencing a narrower range of PO<sub>2</sub> oscillations than what was measured in the chamber. The decrease in the amplitude of PO<sub>2</sub> oscillations experienced by the selected capillaries is proportional to the depth within the tissue (Goldman 2008). The lower saturation values at the peak of the oscillation measured for Cap1 relative to Cap2 can be attributed to the relatively higher mean supply rate for Cap1. The higher the supply rate, the less time the RBCs have to pick up O<sub>2</sub> as they flow across the micro-outlet, which results in lower mean SO<sub>2</sub> values.

Following validation of O<sub>2</sub> delivery through the micro-outlets against controlled chamber PO<sub>2</sub> oscillations, the degree of radial O<sub>2</sub> diffusion from the center of the micro-outlet was

estimated *in vivo*. This was done by measuring the RBC  $SO_2$  in selected capillaries (Cap4 and Cap5, Figure 2.6, panel A) at measured distances from the edge of the micro-outlet and comparing the results to the model calculations. Figure 2.6 (panel D) shows the model's predicted steady state  $O_2$  saturations for the same high and low micro-outlet  $PO_2$  levels used during the *in vivo* measurements. The model shows that the magnitude of the  $SO_2$  perturbation decreases rapidly with radial distance from the edge of the outlet and with depth into the tissue. The diminished effect of the outlet is reflected in the measured  $SO_2$  values for the two capillaries. Although the precise depth of the capillaries were not measured *in vivo*, the approximate depth of 40–50  $\mu m$  suggested by comparing the measured values to the simulation for 123 mmHg  $PO_2$  in the outlet is close to the expected depth. The paired measurements with 1.5 mmHg in the micro-outlet are higher than predicted by the model for this depth into the tissue but the result is not unexpected. With high  $PO_2$  in the tissue the RBC  $SO_2$  under steady state conditions should equilibrate with the surrounding tissue, i.e. the simulation and experiment should match. With low  $PO_2$  in the tissue, the RBCs should be offloading  $O_2$  to the tissue and hence the RBC  $SO_2$  should correspond to a higher  $PO_2$  than the  $PO_2$  in surrounding tissue. These results highlight that the impact of changing  $O_2$  levels in the micro-outlet are limited to the immediate vicinity of the outlet thus meeting our objective of designing a device to investigate local regulation of  $O_2$  supply *in vivo*.

The *in vivo* data presented verify that the 100  $\mu m$  diameter micro-outlets were indeed able to alter  $SO_2$  levels of RBCs in capillaries flowing either directly over or even in close proximity to the outlet. Experimentally measured RBC  $SO_2$  levels fit with our computational model of the  $PO_2$  distribution into the tissue from an interfaced  $O_2$  delivery

micro-outlet. These results delineate an important step towards designing a novel microfluidic device for O<sub>2</sub> delivery to microvascular networks to further investigate regulation of O<sub>2</sub> supply *in vivo*. This device would also allow us to examine the physiological level of O<sub>2</sub> supply set by the microvasculature in the same tissue preparation by recording images at un-stimulated regions distal from the micro-outlets; a goal not feasible with current techniques.

#### **3.1 Introduction**

The microcirculation plays the important role of delivering and regulating the exchange of oxygen (O<sub>2</sub>) and nutrients to surrounding live metabolic tissue. The transport processes in the microcirculation are tightly controlled and highly integrated. Since proper O<sub>2</sub> supply to tissue is critical for cellular function and survival, the mechanisms underlying O<sub>2</sub> transport and distribution have been under thorough investigation. The microvasculature has to continuously adjust erythrocyte distribution and hence O<sub>2</sub> supply to meet the varying demand of metabolic tissue. During exercise, erythrocyte supply rate increases delivering more O<sub>2</sub> carrying erythrocytes to the microvasculature. The highly regulated system implies the presence of signalling components that link tissue O<sub>2</sub> demand with blood flow and microvascular function.

A great amount of evidence suggests the involvement of the erythrocyte as a sensor and a key player in this regulation mechanism (Stein and Ellsworth, 1993, Ellsworth et al., 1995, Ellsworth et al., 2008). Erythrocytes are the carriers of O<sub>2</sub>, bound to hemoglobin, in the microcirculation. Erythrocytes also contain large amounts of adenosine triphosphate (ATP) (Miseta et al., 1993), a potent vasodilator, and are known to release it under

hypoxic conditions (Bergfeld and Forrester, 1992, Jagger et al., 2001, González-Alonso et al., 2002). Once ATP is released, it binds to purinergic receptors (P2Y) on the vascular endothelium eliciting a vaso-dilatory signal which is conducted upstream in the arteriolar tree (Ellsworth et al., 2008). The resulting vaso-relaxation of smooth muscle cells (SMCs) surrounding upstream arterioles increases erythrocyte supply rate to meet the metabolic demand of the hypoxic region downstream that initiated the release of ATP from erythrocytes.

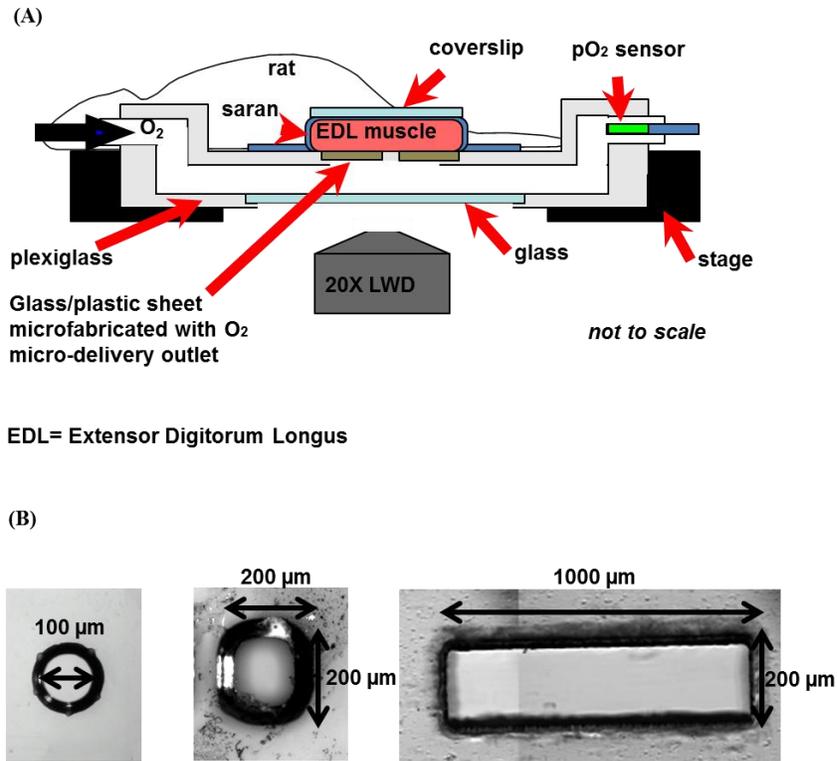

For a long time, arterioles have been investigated as a major site of microvascular signalling (Dulling and Berne, 1970, Duling, 1974, Jackson, 1987). This has been assumed, mainly, due to the large longitudinal  $PO_2$  gradients that exist at the arteriolar level. In terms of ATP-mediated signalling, the presence of SMCs implies that the released ATP will act locally and will instantaneously elicit a signal. However, the relatively short erythrocyte transit times in arterioles are anticipated to largely compromise the localization of this ATP signal, while the parabolic flow profile in the arteriole means only those cells closest to the wall experience the largest change in  $O_2$  saturation ( $SO_2$ ) and hence contribute to the signal. Cells flowing in the centerline will be experiencing a lesser drop in  $SO_2$  and any released ATP will be carried downstream (Ellis et al., 2012).

Venules may also be involved in the regulation of  $O_2$  supply since they act as the collectors of large populations of deoxygenated ATP-releasing erythrocytes. However, the diversity in the erythrocyte  $SO_2$  levels as they drain from various upstream capillaries indicates that venules may only contribute to the overall vaso-dilatory signal (Ellis et al., 2012). Finely tuned regulation of  $O_2$  distribution to specific capillaries or microvascular

units in the microcirculation demands the signal be highly localized. This may only be achieved at the capillary level. Erythrocytes traverse capillaries with long transit times and are in almost direct contact with the capillary endothelium. Hence, released ATP, mediated by erythrocyte deoxygenation, will effectively be transferred to purinergic receptors on the endothelium. Many studies have shown that the capillary endothelium is conductive when locally stimulated by vasodilators (Dietrich, 1989, Dietrich and Tyml, 1992a,b, Song and Tyml, 1993, Collins et al., 1998, Bagher and Segal, 2011). Therefore, we hypothesize that capillaries are able to signal upstream arterioles for changes in erythrocyte supply rate in response to changes in capillary  $SO_2$  level via  $SO_2$  dependent ATP signaling by the erythrocyte (Ellis et al., 2012).

To test this hypothesis, we have been examining the micro-vascular response to local perturbations in tissue  $O_2$  partial pressure ( $PO_2$ ) using a novel  $O_2$  micro-delivery tool (Ghonaim et al., 2011). We have created an  $O_2$  micro-delivery (and removal) system that allows for altering local tissue  $PO_2$  and hence erythrocyte  $SO_2$  in a few selected capillaries at the surface of the Extensor Digitorum Longus (EDL) muscle of the rat (Figure 3.1A). This system replaces the gas exchange chamber originally used in our group to alter surface tissue  $PO_2$  of the entire bottom surface of the muscle (Ellis et al., 2012, Ghonaim et al., 2011). The chamber is positioned in the platform of an inverted microscope and is connected to computer controlled gas flow meters, which allows for capturing video images of the microvascular response to  $PO_2$  perturbations while simultaneously controlling chamber  $PO_2$  levels. Erythrocyte  $SO_2$  values are calculated based on a dual-wavelength image capture system and video sequences are post-

processed to extract functional images and hemodynamic information as previously described (Ellis et al., 1990, Ellis et al., 1992, Japee et al., 2004, Japee et al., 2005a,b).

**Figure 3.1** (A) The novel O<sub>2</sub> micro-delivery approach. The Extensor Digitorum Longus (EDL) rat muscle is surgically exposed and positioned on the viewing platform of an inverted microscope. O<sub>2</sub> is delivered to the surface of the muscle through a micro-outlet patterned in ultrathin glass/plastic sheet (Ghonaim et al., 2011). O<sub>2</sub> levels in the gas exchange chamber near the muscle surface are oscillated using computer controlled flow meters. Real-time videos of the trans-illuminated tissue are monitored and recorded using a dual-wavelength video microscopy system (Ellis et al., 1990, 1992; Japee et al., 2004, 2005a,b) (B) Three designs of the oxygen micro-delivery outlet being tested: circular micro-outlet (~100 μm in diameter), a square micro-slit (200 μm x 200 μm), and a rectangular micro-slit (1000 μm wide x 200 μm long).

In our novel O<sub>2</sub> micro-delivery setup, ultrathin plastic/glass sheet patterned with an O<sub>2</sub> delivery micro-outlet replaces the gas permeable membrane in the original chamber (Ellis et al., 2012, Ghonaim et al., 2011). Data presented earlier (Ghonaim et al., 2011) show that circular micro-delivery outlets (100 μm in diameter) can alter SO<sub>2</sub> in single capillaries flowing directly over the outlet. However, in order to elicit microvascular responses, the optimal outlet dimensions should allow for a sufficient number of capillaries within a network to be stimulated to produce a large enough ATP signal. This should be accomplished while ensuring the high localization of the stimulus to affect only the desired capillaries. This requires testing with various O<sub>2</sub> outlet sizes and dimensions. Combining the possible technical challenges involved in creating multiple designs of the O<sub>2</sub> micro-delivery device with the inherent complexities of the O<sub>2</sub> regulation system led us to develop a computational model for the system under investigation.

Recently, Goldman et al (2012) presented a theoretical mathematical model based on previous work by Goldman and Popel (1999) and Arciero et al (2008) to describe O<sub>2</sub> and ATP transport in the rat EDL microcirculation when using the original O<sub>2</sub> exchange chamber. In this study, we employ the same approach with the objective of calculating SO<sub>2</sub> and ATP changes in selected capillaries flowing over an O<sub>2</sub> delivery outlet of specific dimensions. Three designs of the O<sub>2</sub>-delivery micro-outlet were tested: circular outlet (100 μm in diameter) (Ghonaim et al. 2011), square outlet (200μm x 200μm), and rectangular slit (200μm long x 1000μm wide) (Figure 3.1B). Average capillary SO<sub>2</sub> and ATP level at steady-state were calculated at various chamber PO<sub>2</sub> levels (15, 40 and 150 mmHg) relative to a zero flux boundary condition. In order to simplify the system under investigation, an idealized three dimensional (3D) parallel array capillary geometry has

been used. Simulations were also run on a 3D idealized array geometry in which a terminal arteriole (9  $\mu\text{m}$  in diameter) replaced 4 capillaries and was positioned 30  $\mu\text{m}$  from the bottom tissue surface. These simulations allowed for investigating the potential role of the terminal arteriole in  $\text{O}_2$  regulation. Confirming previous findings (Ghonaim et al., 2011), the results indicated that the maximum amount of radial  $\text{O}_2$  diffusion from an  $\text{O}_2$  delivery micro-outlet is limited to  $\sim 50$   $\mu\text{m}$  beyond the outlet edge, while axial diffusion affects  $\sim 100$   $\mu\text{m}$  of tissue. The rectangular slit has the important property of ensuring that capillaries surrounding the network of interest are all experiencing the same  $\text{PO}_2$  drop, which minimizes re-oxygenation and emphasizes the ATP signal. This design also produces sufficient ATP release in multiple capillaries such that it should be able to consistently elicit micro-vascular responses, although this remains to be confirmed experimentally. The results presented here also predict minimal contribution of terminal arterioles to the net magnitude of ATP emerging from the capillary network although they would participate as  $\text{O}_2$  sources and hence influence the  $\text{O}_2$  distribution. In the future, 3D capillary networks reconstructed from experimental data can be modeled which will provide more realistic data and help to more closely predict changes in various parameters.

## **3.2 Materials and Methods**

### **3.2.1 Oxygen transport model**

In this work,  $\text{O}_2$  transport and ATP transport were modeled in an idealized 3D capillary network consisting of an array of parallel capillaries (oriented in the  $y$  direction). The

computational model of O<sub>2</sub> transport was based on a finite-difference model described by Goldman and Popel (1999, 2000, 2001). In the model, the reaction-diffusion equation below was used to describe time-dependent tissue PO<sub>2</sub>  $P(x,y,z,t)$ :

$$\frac{\partial P}{\partial t} = \left[ 1 + \frac{c_{Mb}}{\alpha} \frac{dS_{Mb}}{dP} \right]^{-1} \left\{ D \nabla^2 P - \frac{1}{\alpha} M(P) + \frac{1}{\alpha} D_{Mb} c_{Mb} \nabla \cdot \left( \frac{dS_{Mb}}{dP} \nabla P \right) \right\} \quad (1)$$

where  $D$  is the tissue O<sub>2</sub> diffusion coefficient,  $\alpha$  is the tissue O<sub>2</sub> solubility, and  $M(P)$  is consumption rate of O<sub>2</sub> in tissue (Table 1). O<sub>2</sub> transport in tissue was facilitated by the presence of myoglobin where  $c_{Mb}$  is the myoglobin concentration,  $D_{Mb}$  is the myoglobin diffusion coefficient, and  $S_{Mb}(P) = P/(P + P_{50,Mb})$  is the myoglobin SO<sub>2</sub>. Convective transport of O<sub>2</sub> in the micro-vessels at each axial location  $y$  was described using the following time-dependent mass balance equation for capillary SO<sub>2</sub>,  $S(y,t)$ :

$$\frac{\partial S}{\partial t} = - \left[ C + \alpha_b \frac{dP_b}{dS} \right]^{-1} \left\{ -u \left[ \tilde{C} + \tilde{\alpha}_b \frac{dP_b}{dS} \right] \frac{\partial S}{\partial y} - \frac{1}{\pi R} \oint j \cdot d\theta \right\} \quad (2)$$

where  $u$  is the mean blood velocity,  $R$  is the capillary radius,  $j$  is the O<sub>2</sub> flux at  $(y, \theta)$  out of the capillary,  $C$  and  $\tilde{C}$  are blood O<sub>2</sub>-binding capacities, respectively, directly related to hematocrit:

$$C = H_T C_{Hb}$$

$$\tilde{C} = H_D C_{Hb}$$

where  $H_T$  is tube (volume-weighted) hematocrit,  $H_D$  is discharge (flow-averaged) hematocrit, and  $C_{Hb}$  is the binding capacity of hemoglobin (Table 1) (Goldman and Popel 2001).  $P_b$  is the blood PO<sub>2</sub>, and  $\alpha_b$  and  $\tilde{\alpha}_b$  are volume- and flow-weighted blood O<sub>2</sub> solubilities, respectively (Goldman and Popel, 2001), where,

$$\alpha_b = H_T \alpha_{cell} + (1 - H_T) \alpha_{pl}$$

$$\tilde{\alpha}_b = H_D \alpha_{cell} + (1 - H_D) \alpha_{pl}$$

where  $\alpha_{cell}$  and  $\alpha_{pl}$  are the  $O_2$  solubilities inside the erythrocyte and in the plasma (Goldman and Popel 2001). The  $O_2$  flux at the capillary-tissue interface was given by:

$$j = \kappa (P_b - P_w) \quad (3)$$

where  $\kappa$  is the mass transfer coefficient and  $P_w$  is the tissue  $PO_2$  at the capillary surface.  $\kappa$  is a function of hematocrit as it describes the effect of RBC spacing on  $O_2$  diffusion and exchange between capillary and tissue (Eggleton et al., 2000). At the capillary surface, the boundary condition was specified as:

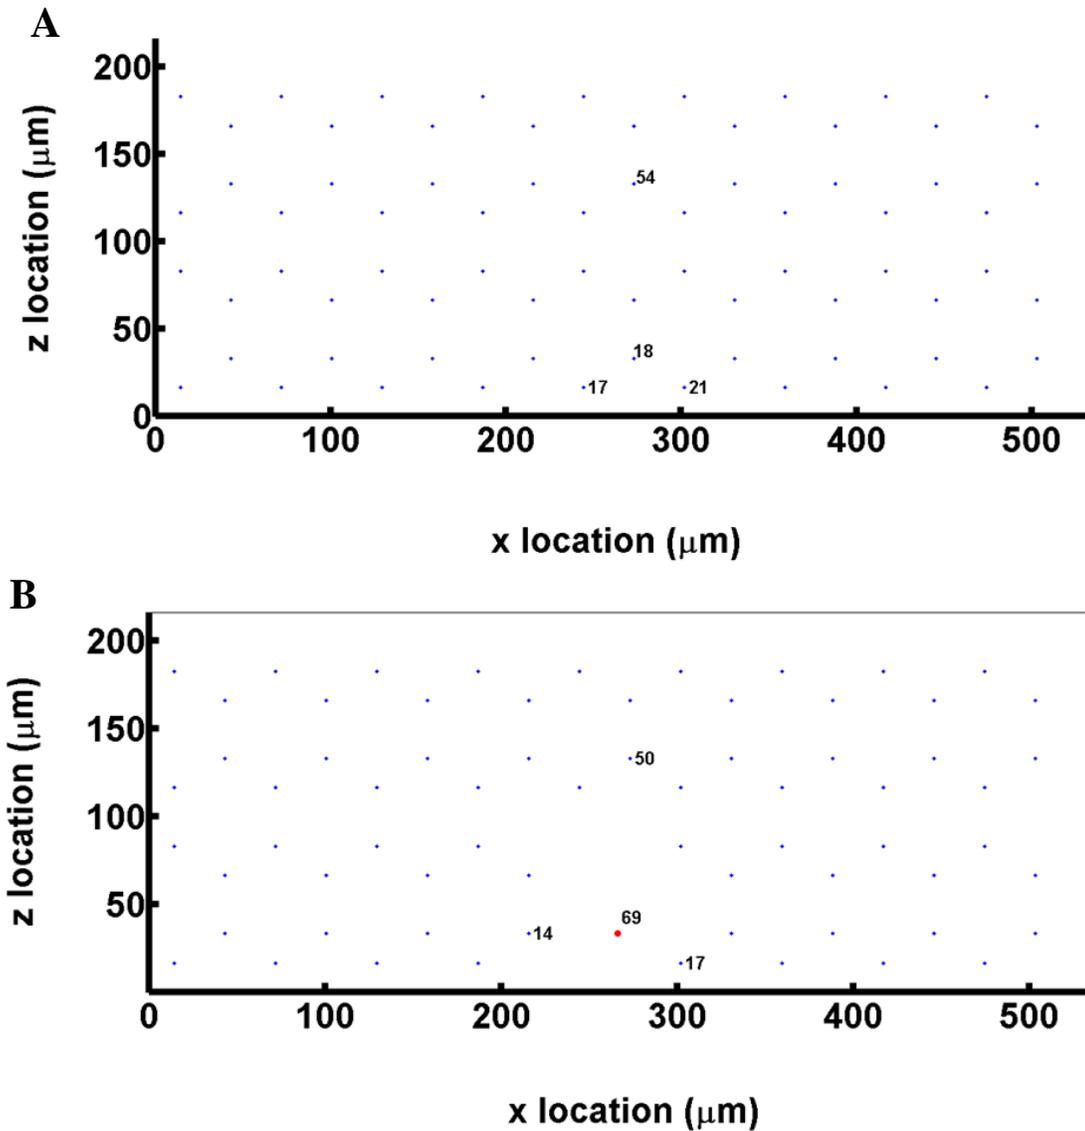

$$-D\alpha \frac{\partial P_w}{\partial n} = j \quad (4)$$

where  $n$  is the unit vector normal to the capillary surface and  $j$  is given by equation (3). In the model presented here, zero  $O_2$  flux conditions (no  $O_2$  exchange across tissue boundary) were specified at the tissue boundaries, except where  $PO_2$  was fixed on part or all of the bottom surface to represent the effect of the  $O_2$  exchange chamber (see below). As in the model described by Goldman and Popel (1999), Michaelis-Menten consumption kinetics,  $M = M_0 P / (P + P_{cr})$ , and the Hill equation for the oxyhemoglobin saturation curve,  $S(P) = P^n / (P^n + P_{50}^n)$ , were used along with the above  $O_2$  transport equations to calculate the tissue  $O_2$  transport.

Hemodynamic parameters (erythrocyte mean velocity,  $v_{rbc}$ , and hematocrit,  $H_T$ ) were determined from *in vivo* experimental measurements in the EDL muscle of the rat. The

capillary network consisted of 72 parallel capillaries, each of which was discretized into 50 cylindrical segments, and the tissue domain surrounding the capillaries had dimensions of 216 x 532 x 500  $\mu\text{m}$  and was discretized into 7,304,853 computational nodes using a grid spacing of approximately 2  $\mu\text{m}$  (Figure 3.2A). Capillary entrance  $\text{SO}_2$  (65%) and the tissue  $\text{O}_2$  consumption rate ( $1.5 \times 10^{-4}$  ml  $\text{O}_2/\text{ml}/\text{s}$ ) were set based on previous experimental data (Fraser et al. 2012).

For simulations that included a terminal arteriole in the 3D network geometry, the arteriole (9  $\mu\text{m}$  in diameter) was positioned approximately 30  $\mu\text{m}$  from the bottom tissue surface and replaced 4 capillaries in the original parallel array capillary geometry (Figure 3.2B). Simulations including the arteriole were run at both 65% and 80% arteriolar entrance  $\text{SO}_2$ .

**Figure 3.2** (A) A cross sectional view of the idealized capillary parallel-array geometry showing the positioning and numbering of the 72 hexagonally arranged capillaries in the modeled network (B) A cross sectional view of the idealized capillary parallel array geometry with a terminal arteriole (vessel 69, 9  $\mu\text{m}$  in diameter) replacing 4 capillaries within 30  $\mu\text{m}$  from bottom tissue surface.

### 3.2.2 ATP transport model

ATP transport in the idealized 3D capillary network was modeled as described by Goldman et al 2012, based on the O<sub>2</sub> transport mathematical model described earlier (Goldman and Popel 2000). Using a capillary entrance ATP concentration [ATP] of zero, plasma [ATP] was calculated by using a finite-difference method to solve the following continuum partial differential equation (Goldman et al 2012):

$$\begin{aligned} (1-H_T) \frac{\partial}{\partial t} [ATP] = & -u(1-H_D) \frac{\partial}{\partial y} [ATP] \\ & +H_T C_0 (1-C_1 S) - \frac{2}{R} k_d [ATP] \end{aligned} \quad (5)$$

where  $u$  is the mean blood velocity at axial location  $y$ ,  $H_D$  and  $H_T$  are the discharge and tube hematocrit, respectively, and  $R$  is the capillary radius.  $C_0$  and  $C_1$  (see Table 3) are constants used to linearly approximate the ATP release rate as a function of SO<sub>2</sub>, while  $k_d$  provides an approximation of ATP degradation by the endothelium as previously described (Arciero et al., 2008).

To calculate the steady-state distributions of tissue PO<sub>2</sub> as well as capillary SO<sub>2</sub> and [ATP], time-dependent O<sub>2</sub> transport and ATP transport simulations were run, using zero initial conditions for all variables, until there were minimal changes in tissue O<sub>2</sub> consumption and PO<sub>2</sub>, and capillary O<sub>2</sub> flux, SO<sub>2</sub> and [ATP] between consecutive time steps.

### **3.2.3 Tissue PO<sub>2</sub> boundary conditions used to model oxygen exchange chamber**

For the idealized capillary geometry, 3D tissue PO<sub>2</sub> distribution and capillary [ATP] at steady state were calculated for O<sub>2</sub> delivery using a full gas exchange chamber, a circular micro-outlet (100 μm in diameter), a square micro-outlet (200 μm x 200 μm), or a rectangular micro-slit (1000 μm wide x 200 μm long). For each chamber type, simulations were run at 3 PO<sub>2</sub> boundary conditions either over full surface (with full gas exchange chamber) or only at the micro-slit opening: 15 mmHg, 40 mmHg and 150 mmHg. For the cases in which the PO<sub>2</sub> boundary condition is altered only at the micro-slit opening, the rest of the tissue surrounding the micro-slit is set to zero O<sub>2</sub> flux boundary condition. The results from all simulations were compared to a fourth control case in which full surface is set to zero O<sub>2</sub> flux boundary condition.

For the idealized capillary geometry that includes the terminal arteriole, O<sub>2</sub> diffusion was modeled for a full gas exchange chamber or a rectangular micro-slit (1000 μm wide x 200 μm long) at the four PO<sub>2</sub> boundary conditions discussed above. Each set of simulations was run with arteriolar entrance SO<sub>2</sub> of 65% or 80%. Table 2 lists the summary of simulations and boundary conditions used in this study.

Parameter	Description	Value
$\alpha$	O <sub>2</sub> solubility	$3.89 \times 10^{-5} \text{ ml O}_2 \text{ ml}^{-1} \text{ mmHg}^{-1}$
$D$	O <sub>2</sub> diffusion coefficient	$2.41 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$
$P_{cr}$	Critical PO <sub>2</sub>	0.5 mmHg
$c_{Mb}$	myoglobin concentration	$1.02 \times 10^{-2} \text{ ml O}_2 \text{ ml}^{-1}$
$D_{Mb}$	myoglobin diffusion coefficient	$3 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$
$P_{50}$	Blood PO <sub>2</sub> at 50% hemoglobin SO <sub>2</sub>	37 mmHg
$n$	Hill exponent	2.7
$P_{50,Mb}$	PO <sub>2</sub> at 50% myoglobin SO <sub>2</sub>	5.3 mmHg
$v_{rbc}$	erythrocyte mean velocity	$1.45 \times 10^{-2} \text{ cm s}^{-1}$
$C_{HB}$	binding capacity of hemoglobin	0.52 ml O <sub>2</sub> ml <sup>-1</sup>
$H_T$	Tube hematocrit	0.19
$H_D$	Discharge Hematocrit	0.2
$C_0$	Constant approximating linear ATP release rate as a function of SO <sub>2</sub>	$1.4 \times 10^{-9} \text{ mol s}^{-1} \cdot \text{cm}^{-3}$
$C_1$	Constant approximating linear ATP release rate as a function of SO <sub>2</sub>	0.891
$k_d$	ATP degradation rate	$2.0 \times 10^{-4} \text{ cm s}^{-1}$

**Table 3.1** Parameter values used in oxygen and ATP transport simulations.

<b>Network specifications</b>	<b>Chamber type tested</b>	<b>Corresponding figure in manuscript</b>	<b>PO<sub>2</sub> condition at chamber outlet (in each chamber type tested)</b>
Capillary array	Full Chamber	3.3	• Zero O <sub>2</sub> flux (Control)
	Circle	3.4	• 40 mmHg
	Square	3.5	• 15 mmHg
	Rectangle	3.6	• 150 mmHg
Capillary array with arteriole (entrance SO <sub>2</sub> =65%)	Full Chamber	3.8	• Zero O <sub>2</sub> flux (Control) • 40 mmHg
	Rectangle	3.10	• 15 mmHg • 150 mmHg

## 3.3 Results

### 3.3.1 Mathematical modelling of $\text{SO}_2$ -dependent ATP release in capillary networks in response to localized tissue $\text{PO}_2$ perturbations

In this study, the release of ATP in capillaries mediated by tissue hypoxia and the de-saturation of hemoglobin was modeled in a 3D idealized parallel capillary network. The dependence of the magnitude of total ATP release on the number of de-oxygenated capillaries was also examined. Based on our previously described experimental work (Ghonaim et al. 2011), we mathematically simulated  $\text{O}_2$  delivery to and removal from selected capillaries on the surface of skeletal muscle tissue (rat EDL) using three designs of  $\text{O}_2$  exchange micro-outlets used in our *in vivo* experiments (Figure 3.1B). In order to compare local  $\text{O}_2$  perturbations using the micro-outlets to global perturbations using the full gas exchange chamber (Ellis et al., 2012, Ghonaim et al. 2011),  $\text{O}_2$  delivery to and removal from the entire bottom tissue surface was also modeled. For each set of simulations, 3D tissue  $\text{PO}_2$  distribution profiles and corresponding 3D capillary [ATP] maps were generated. Plots of calculated  $\text{SO}_2$  and [ATP] along the length of selected capillaries (21, 18, 17, 54) at steady state were also created. All simulations were run using software written in Fortran, and the results were analyzed and the plots were produced using MATLAB.

### **3.3.1.1 Full surface gas exchange chamber**

In this set of simulations, the 3D PO<sub>2</sub> distribution in the tissue and corresponding SO<sub>2</sub> and [ATP] distribution along capillary length were modeled for the control scenario in which the full bottom tissue surface is exposed to PO<sub>2</sub> perturbations. This would experimentally simulate using the full gas exchange chamber. As shown in Figure 3.3, at 40 mmHg, steady-state tissue PO<sub>2</sub> and capillary [ATP] distributions are comparable to the no-flux control condition. At the venular end of the capillaries, SO<sub>2</sub> values ranged from ~50% for surface capillaries (# 21, 18, and 17) to ~40% for capillaries deeper than 100 μm into the tissue (capillary 54), and the corresponding capillary [ATP] values were within 15% of those at zero O<sub>2</sub> flux boundary condition. However, under imposed tissue hypoxia (15 mmHg), the surface capillaries dropped their SO<sub>2</sub> by approximately 70% which corresponded to ~40% higher steady state capillary [ATP] relative to zero flux condition (Figure 3.3C). This was clearly depicted in the corresponding vessel map (Figure 3.3B). The deeper capillary (54) was less affected with ~30% lower hemoglobin SO<sub>2</sub> and ~12% increase in ATP release relative to zero flux. Exposing the full tissue surface to relatively high chamber PO<sub>2</sub> (150 mmHg) had the most significant impact on [ATP] in the capillary network. At 150 mmHg, hemoglobin SO<sub>2</sub> in both surface and deep tissue capillaries converged to ~100% with ~70% decrease in steady state [ATP] relative to no-flux (Figure 3.3C). The depth of the PO<sub>2</sub> perturbation into the tissue when using the full gas exchange chamber was ~ 100 μm as shown in the 3D PO<sub>2</sub> profiles (Figure 3.3A).

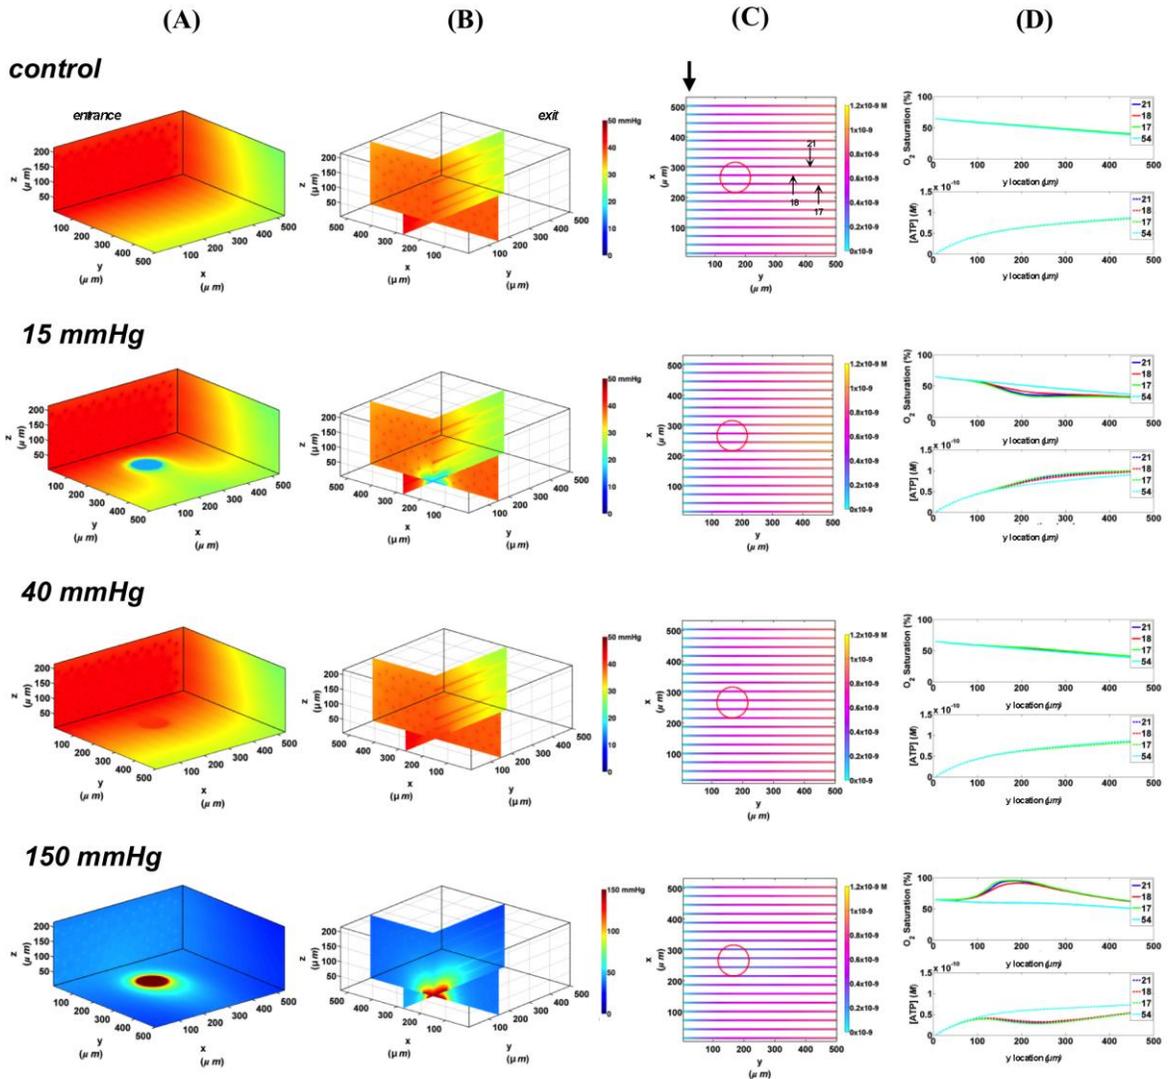

**Figure 3.3** Simulations of 3D  $PO_2$  and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (72 hexagonally packed capillaries). In these simulations, we are modeling  $O_2$  delivery to the bottom tissue surface using the full gas exchange chamber (Ellis et al., 2012; Ghonaim et al., 2011). Full bottom tissue surface is exposed to 15 mmHg, 40 mmHg, or 150 mmHg chamber  $PO_2$  level relative to a zero flux

control boundary condition **(A)** Spatial 3D tissue  $PO_2$  distribution (mmHg) at capillary entrance perspective **(B)** a capillary exit perspective showing combined X-Z plane slice at  $Y=150\ \mu\text{m}$  and Y-Z plane slice at  $X=277\ \mu\text{m}$  **(C)** bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the capillaries. Bolded arrow marks capillary entrance **(D)** Plots of  $SO_2$  (%) and [ATP] changes along capillary length in selected capillaries (# 21, 18, 17, 54) marked by arrows on the vessel map. Capillaries 21 and 17 are  $16\ \mu\text{m}$  from the tissue surface, capillary 18 is  $33\ \mu\text{m}$  from tissue surface, and capillary 54 is deeper in the tissue, at  $133\ \mu\text{m}$ , and hence it is not shown in the current perspective of the vessel map. Note change in  $PO_2$  scale from 0 to 50 mmHg in first three cases to 0 to 150 mmHg when surface is exposed to 150 mmHg.

### **3.3.1.2 Circular $O_2$ delivery micro-outlet**

To investigate the effect of limiting the number of capillaries stimulated by local tissue  $PO_2$  perturbations, we started by modeling capillary  $SO_2$  and [ATP] changes when using a circular  $O_2$  micro-outlet ( $100\ \mu\text{m}$  in diameter, see Figure 3.1). Similar to previously discussed data (Ghonaim et al 2011), substantive changes in local tissue  $PO_2$ , due to diffusion outwards from the circular outlet, is limited to less than  $\sim 50\ \mu\text{m}$ , as shown in the 3D tissue  $PO_2$  profiles (Figure 3.4A). Also, the hypoxic and hyperoxic stimuli were highly localized to only those capillaries directly over the micro-outlet (17, 18, 21) as shown in the vessel maps (Figure 3.4B). At 40 mmHg chamber  $PO_2$  level, calculated

capillary  $\text{SO}_2$  and [ATP] were in close agreement with the no-flux control for both surface and deep tissue capillaries with values being within ~1% and ~3%, respectively (Figure 3.4C). Under imposed hypoxia, the capillary  $\text{SO}_2$  dropped as capillaries crossed the micro-outlet region reaching a minimum value ~40  $\mu\text{m}$  downstream of the outlet after which  $\text{SO}_2$  levels increased slightly due to re-oxygenation by surrounding capillaries. At the venular end, steady state  $\text{SO}_2$  levels in surface capillaries were 15% lower relative to zero flux while capillary 54 experienced only a 6% drop in  $\text{SO}_2$ . This corresponded to only 10% increase in [ATP] in surface capillaries while [ATP] in capillary 54 remained unchanged relative to zero flux. At 150 mmHg, the increase in capillary  $\text{SO}_2$  level is observed directly over the micro-outlet region reaching a maximum at the outlet exit. The capillary  $\text{SO}_2$  levels dropped sharply downstream of the outlet due to  $\text{O}_2$  diffusion into adjacent capillaries and tissue. Surface capillary  $\text{SO}_2$  decreased to ~63% and deep tissue capillaries to 51% at ~200  $\mu\text{m}$  downstream of the outlet. This corresponded to ~40% decrease in [ATP] in surface capillaries and ~20% decrease in [ATP] of deeper tissue capillaries relative to zero flux condition.

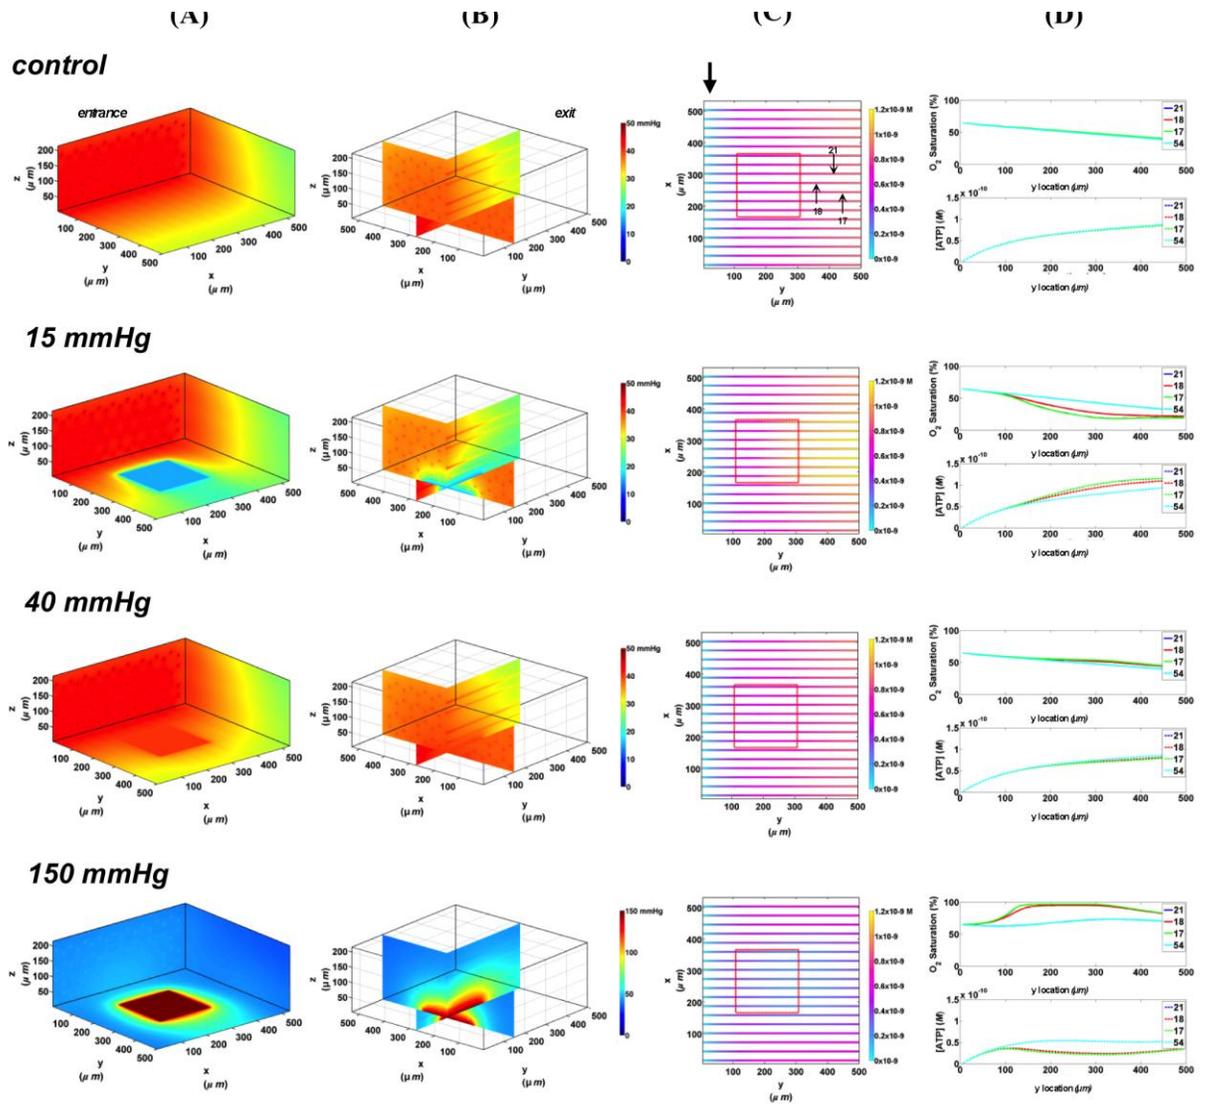

**Figure 3.4** Simulations of 3D  $PO_2$  and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (72 hexagonally packed capillaries). In these simulations, we are modeling  $O_2$  delivery through a circular oxygen micro-delivery outlet (100  $\mu m$  in diameter) to bottom tissue surface using novel micro-delivery approach (see Figure 3.1). Tissue surface directly on top of the micro-delivery outlet is exposed to 15

mmHg, 40 mmHg, or 150 mmHg chamber PO<sub>2</sub> level relative to a zero flux control boundary condition (A) Spatial 3D tissue PO<sub>2</sub> distribution (mmHg) at capillary entrance perspective (B) a capillary exit perspective showing combined X-Z plane slice at Y=150 μm and Y-Z plane slice at X= 277 μm (C) bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the capillaries. Bolded arrow marks capillary entrance (D) Plots of SO<sub>2</sub> (%) and [ATP] changes along capillary length in selected capillaries (21, 18, 17, 54) marked by arrows on the vessel map. Capillaries 21 and 17 are 16 μm from tissue surface, capillary 18 is 33 μm from tissue surface, and capillary 54 is deeper in the tissue, at 133 μm, and hence it is not shown in the current perspective of the vessel map.

### **3.3.1.3 Square O<sub>2</sub> delivery micro-outlet**

Next, we simulated the effect of increasing the area of O<sub>2</sub> exchange, and hence perturbing a greater number of capillaries, by simulating an O<sub>2</sub> delivery micro-outlet 200 μm x 200 μm square. Similar to the circular micro-outlet design and as previously described (Ghonaim et al 2011), the change of local tissue PO<sub>2</sub> surrounding the square outlet is limited to less than ~50 μm, as shown in the 3D tissue PO<sub>2</sub> profiles (Figure 3.5A). In the case of the square micro-outlet, a larger number of surface capillaries experience the PO<sub>2</sub> perturbations, 7 of which were directly over the micro-outlet (Figure 3.5B). Also, capillaries at both sides of those directly over the outlet seemed to be slightly affected by the PO<sub>2</sub> perturbations. At 40 mmHg, calculated SO<sub>2</sub> and capillary [ATP] distributions were similar to the no-flux control with surface capillaries having 15% higher SO<sub>2</sub> and

10% lower [ATP] values relative to zero flux condition (Figure 3.5C). As observed with the circular micro-outlet, re-oxygenation of stimulated capillaries following imposed hypoxia (15 mmHg) was at  $\sim 40 \mu\text{m}$  downstream of the square micro-outlet (Figure 3.5C). At the capillary venular end,  $\text{SO}_2$  level of surface capillaries dropped by  $\sim 51\%$  while capillary 54 experienced only a 15% drop in  $\text{SO}_2$  relative to zero flux. This corresponded to  $\sim 32\%$  increase in [ATP] in surface capillaries while only 7% increase in [ATP] in capillary 54 relative to zero flux. At 150 mmHg, capillary  $\text{SO}_2$  levels increased across the micro-delivery outlet reaching maximum values at the venular end of the outlet region. Similar to the results observed with the circular micro-outlet,  $\text{SO}_2$  values sharply dropped downstream of the square micro-outlet bringing surface capillary  $\text{SO}_2$  to  $\sim 83\%$  and deeper capillaries to  $\sim 70\%$   $\sim 200 \mu\text{m}$  downstream of the outlet. This corresponded to  $\sim 66\%$  decrease in [ATP] in surface capillaries and  $\sim 42\%$  decrease in [ATP] of deeper tissue capillaries.

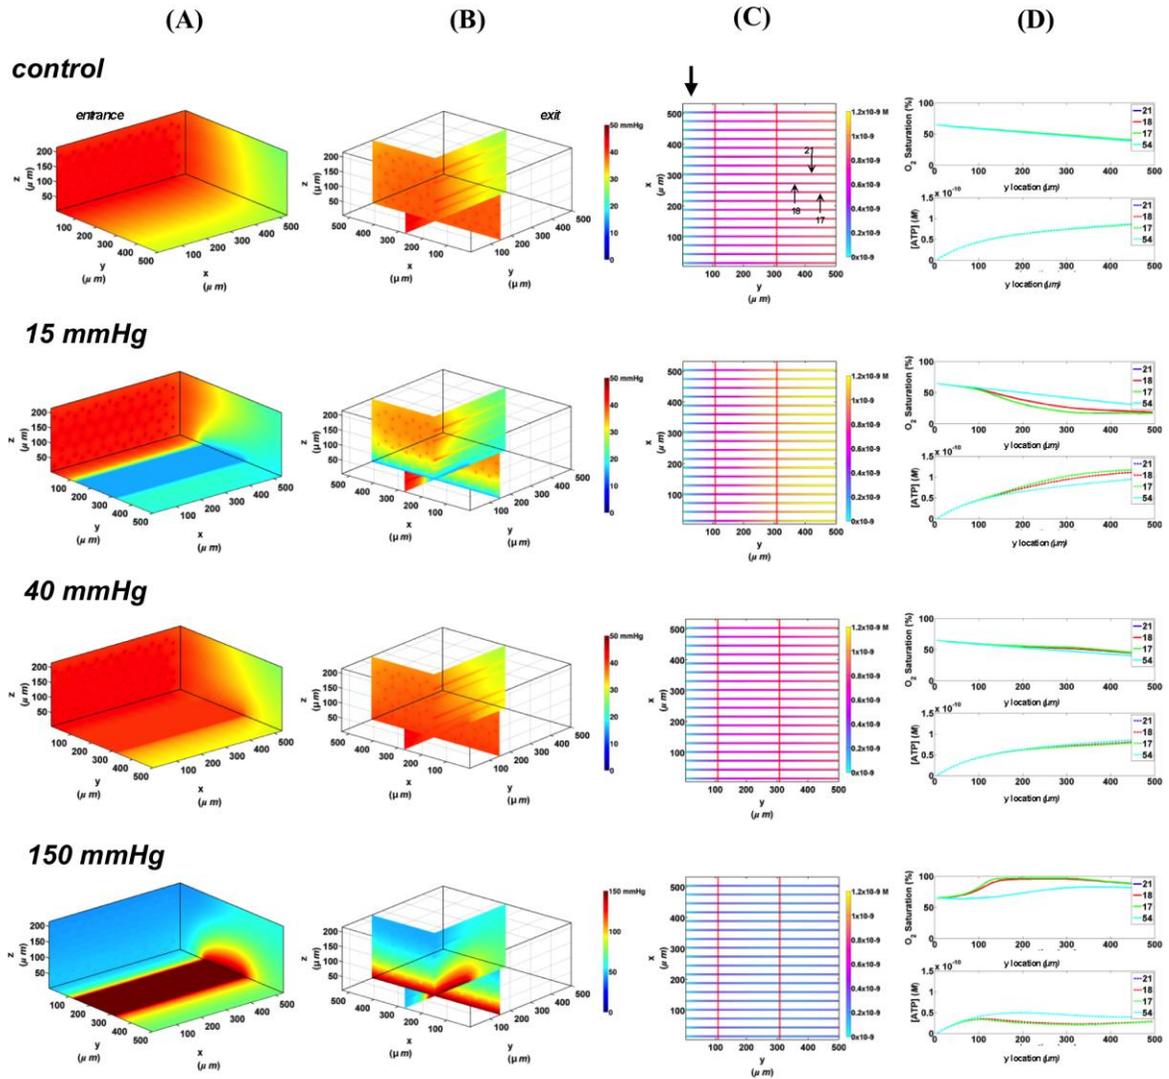

**Figure 3.5** Simulations of 3D  $PO_2$  and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (72 hexagonally packed capillaries). In these simulations, we are modeling  $O_2$  delivery through a square oxygen micro-delivery outlet (200  $\mu m \times 200 \mu m$ ) to bottom tissue surface using our previously described novel micro-

delivery approach (see Figure 3.1). Tissue surface directly on top of the micro-delivery outlet is exposed to 15 mmHg, 40 mmHg, or 150 mmHg chamber PO<sub>2</sub> level relative to a zero flux control boundary condition (A) Spatial 3D tissue PO<sub>2</sub> distribution (mmHg) at capillary entrance perspective (B) a capillary exit perspective showing combined X-Z plane slice at Y=150 μm and Y-Z plane slice at X= 277 μm (C) bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the capillaries. Bolded arrow marks capillary entrance (D) Plots of SO<sub>2</sub> (%) and [ATP] changes along capillary length in selected capillaries (21, 18, 17, 54) marked by arrows on the vessel map. Capillaries 21 and 17 are 16 μm from tissue surface, capillary 18 is 33 μm from tissue surface, and capillary 54 is deeper in the tissue, at 133 μm, and hence it is not shown in the current perspective of the vessel map.

#### **3.3.1.4 Rectangular O<sub>2</sub> delivery micro-slit**

The largest dimensions for an O<sub>2</sub> delivery micro-outlet currently being tested in our *in vivo* studies are for a rectangular micro-slit (1000 μm wide x 200 μm long). Since the 3D tissue dimensions in our computational model are less than the width of the experimental micro-slit, the effect of the slit extends to both edges of the tissue allowing us to visualize the depth of the PO<sub>2</sub> distribution into the tissue. As shown in the 3D PO<sub>2</sub> plots (Figure 3.6A), the PO<sub>2</sub> perturbations extended ~100 μm into the tissue with local tissue PO<sub>2</sub> changes similar to what was observed with other outlet designs. All surface capillaries

shown on the vessel map are affected by the  $PO_2$  perturbation as the outlet covers the entire surface width (Figure 3.6B). At 40 mmHg, calculated  $SO_2$  and capillary [ATP] distributions were similar to the no-flux control with surface capillaries having 17% higher  $SO_2$  and 10.3% lower [ATP] values relative to zero flux  $O_2$  boundary condition (Figure 3.6C). Under imposed hypoxia (15 mmHg), re-oxygenation of de-saturated surface capillaries was not observed within 200  $\mu m$  downstream of the micro-slit. However, capillary  $SO_2$  seemed to plateau approximately 100  $\mu m$  downstream of the micro-slit. At the capillary venular end,  $SO_2$  level of surface capillaries dropped by ~56% while capillary 54 experienced a ~20% drop in  $SO_2$  relative to zero flux condition. This corresponded to ~35% increase in [ATP] in surface capillaries and only 8% increase in [ATP] in capillary 54 relative to zero flux. At 150 mmHg, capillary  $SO_2$  levels increased across the micro-delivery outlet reaching maximum values at the venular end of the outlet region. Similar to the results observed with the previously discussed micro-outlet designs,  $SO_2$  values instantly dropped downstream of the rectangular micro-slit bringing surface capillary  $SO_2$  to ~90% and deep capillaries to ~80% ~200  $\mu m$  downstream of the outlet. This corresponded to ~69% decrease in [ATP] in surface capillaries and ~55% decrease in [ATP] for deeper tissue capillaries.

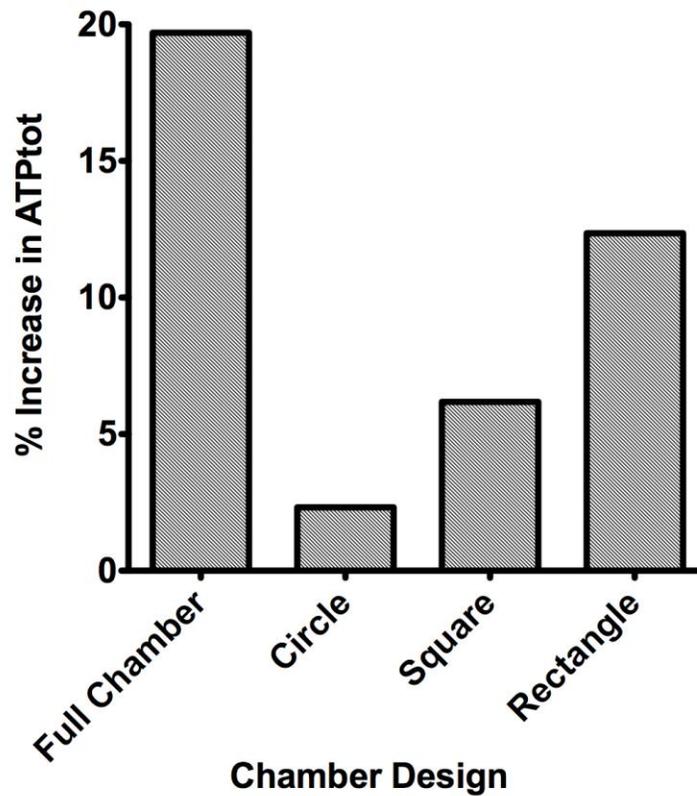

**Figure 3.6** Simulations of 3D  $PO_2$  and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (72 hexagonally packed capillaries). In these simulations, we are modeling  $O_2$  delivery through a rectangular oxygen micro-delivery outlet (1000  $\mu m$  wide x 200  $\mu m$  long) to the bottom tissue surface using our previously described novel micro-delivery approach (see Figure 3.1). The tissue surface directly on

top of the micro-delivery outlet is exposed to 15 mmHg, 40 mmHg, or 150 mmHg chamber PO<sub>2</sub> level relative to a zero flux control boundary condition (A) Spatial 3D tissue PO<sub>2</sub> distribution (mmHg) at capillary entrance perspective (B) a capillary exit perspective showing combined X-Z plane slice at Y=150 μm and Y-Z plane slice at X=277 μm (C) bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the capillaries. Bolded arrow marks capillary entrance (D) Plots of SO<sub>2</sub> (%) and [ATP] changes along capillary length in selected capillaries (21, 18, 17, 54) marked by arrows on the vessel map. Capillaries 21 and 17 are 16 μm from tissue surface, capillary 18 is 33 μm from tissue surface, and capillary 54 is deeper in the tissue, at 133 μm, and hence it is not shown in the current perspective of the vessel map.

### ***3.3.1.5 Comparing change in relative ATP magnitude in response to varying the area of imposed tissue hypoxia***

The change in the total magnitude of ATP (ATP<sub>tot</sub>) in the modeled network when imposing a hypoxic challenge (15 mmHg boundary condition) was calculated as percent increase above ATP<sub>tot</sub> at zero flux (Figure 3.7). Percent increase in ATP magnitude in the network was compared when exposing all of the bottom tissue surface to hypoxia (full chamber) or locally using the three micro-outlet designs discussed above. As shown in Figure 3.7, the total ATP magnitude increased with increases in micro-outlet dimensions and essentially the number of capillaries experiencing the PO<sub>2</sub> drop. The

percent increase in  $ATP_{tot}$  was more than doubled when locally perturbing tissue  $PO_2$  using the rectangular micro-slit compared to the other micro-outlet designs. The total ATP magnitude calculated when limiting the area of tissue hypoxia using the rectangular micro-slit was only 38% lower relative to a full exposed surface (Figure 3.7). The increase in the total ATP magnitude in a network exposed to local hypoxia was minimal (~2%) as modeled when using the circular micro-outlet and only 6% above that at zero flux when using the square micro-outlet.

**Figure 3.7** Percent increase in the total magnitude of ATP ( $ATP_{tot}$ ) relative to zero flux control boundary condition calculated for idealized parallel capillary network with no

arteriole at 15 mmHg chamber  $PO_2$  level. Percent increase in ATP magnitude in the network were calculated when the entire bottom tissue surface is exposed to the  $PO_2$  perturbation using a full gas exchange chamber or locally using a circular (100  $\mu\text{m}$  in diameter), square (200  $\mu\text{m}$  x 200  $\mu\text{m}$ ) or rectangular  $O_2$  delivery micro-slit (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long).

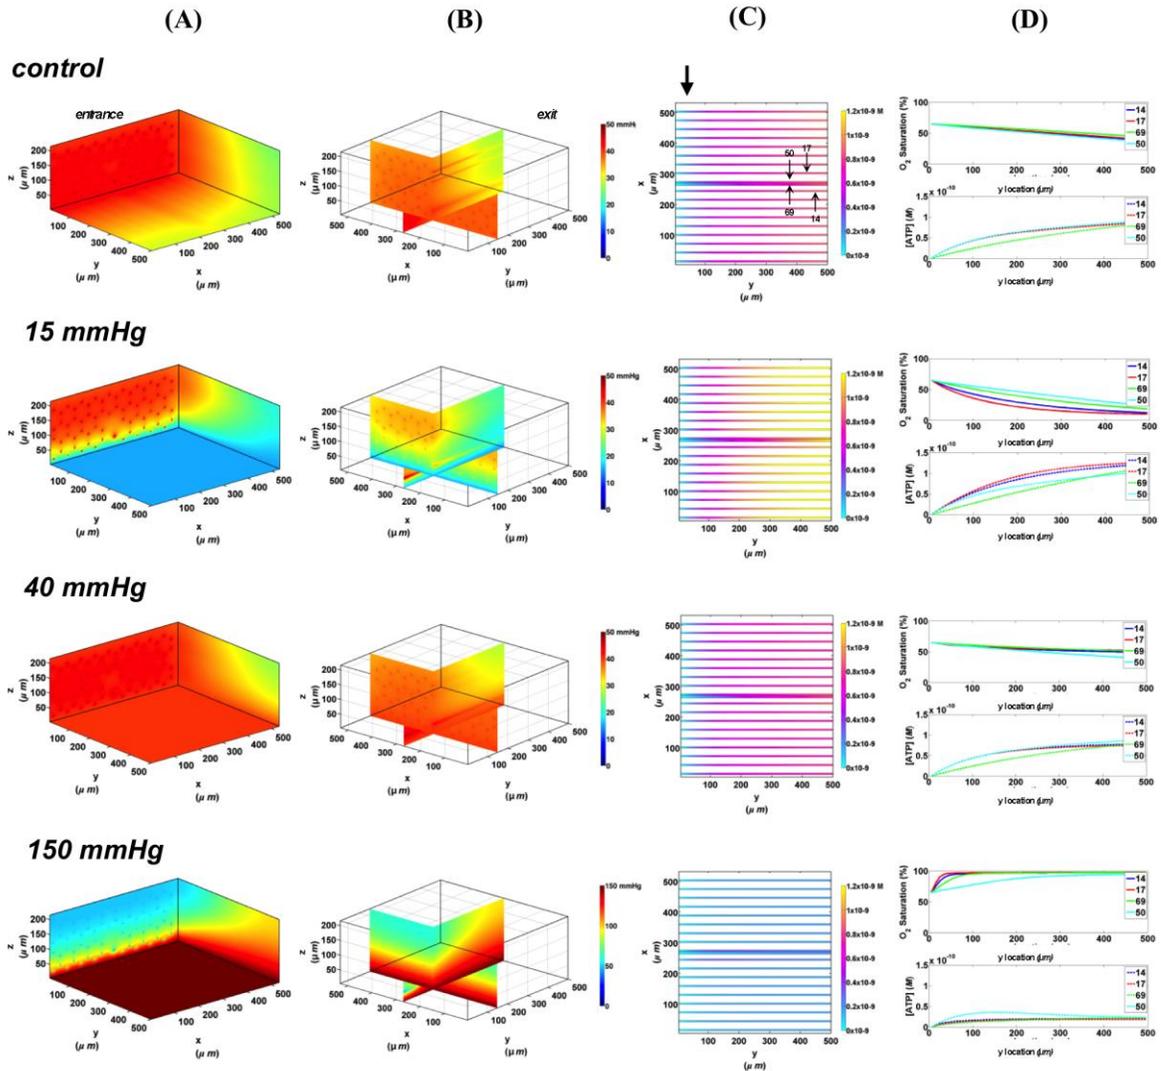

### **3.3.2 Mathematical modelling of arteriolar $SO_2$ and ATP concentration in response to localized tissue $PO_2$ perturbations**

In order to investigate the role terminal arterioles play in regulating  $SO_2$ -mediated ATP signaling in capillary networks, particularly in the EDL muscle where larger arterioles are located much deeper in the tissue, the 3D idealized capillary geometry was modified to include a terminal arteriole, 9  $\mu\text{m}$  in diameter, positioned 30  $\mu\text{m}$  away from bottom tissue surface. The 3D tissue  $PO_2$  distribution, as well as  $SO_2$  and [ATP] in the arteriole (vessel 69) and in the surrounding surface (capillaries 14 and 17) and deep tissue capillaries (represented by capillary 50), were modeled. Simulations were run for the case in which the full tissue surface is exposed to  $PO_2$  perturbations (original gas exchange chamber) and for the case of spatially limited  $O_2$  delivery using the rectangular  $O_2$  delivery micro-slit. Also, the effect of varying arteriolar entrance  $SO_2$  on the overall magnitude of ATP in response to altered tissue  $PO_2$  was examined.

### **3.3.2.1 Full surface gas exchange chamber at 65% and 80% arteriolar entrance $SO_2$**

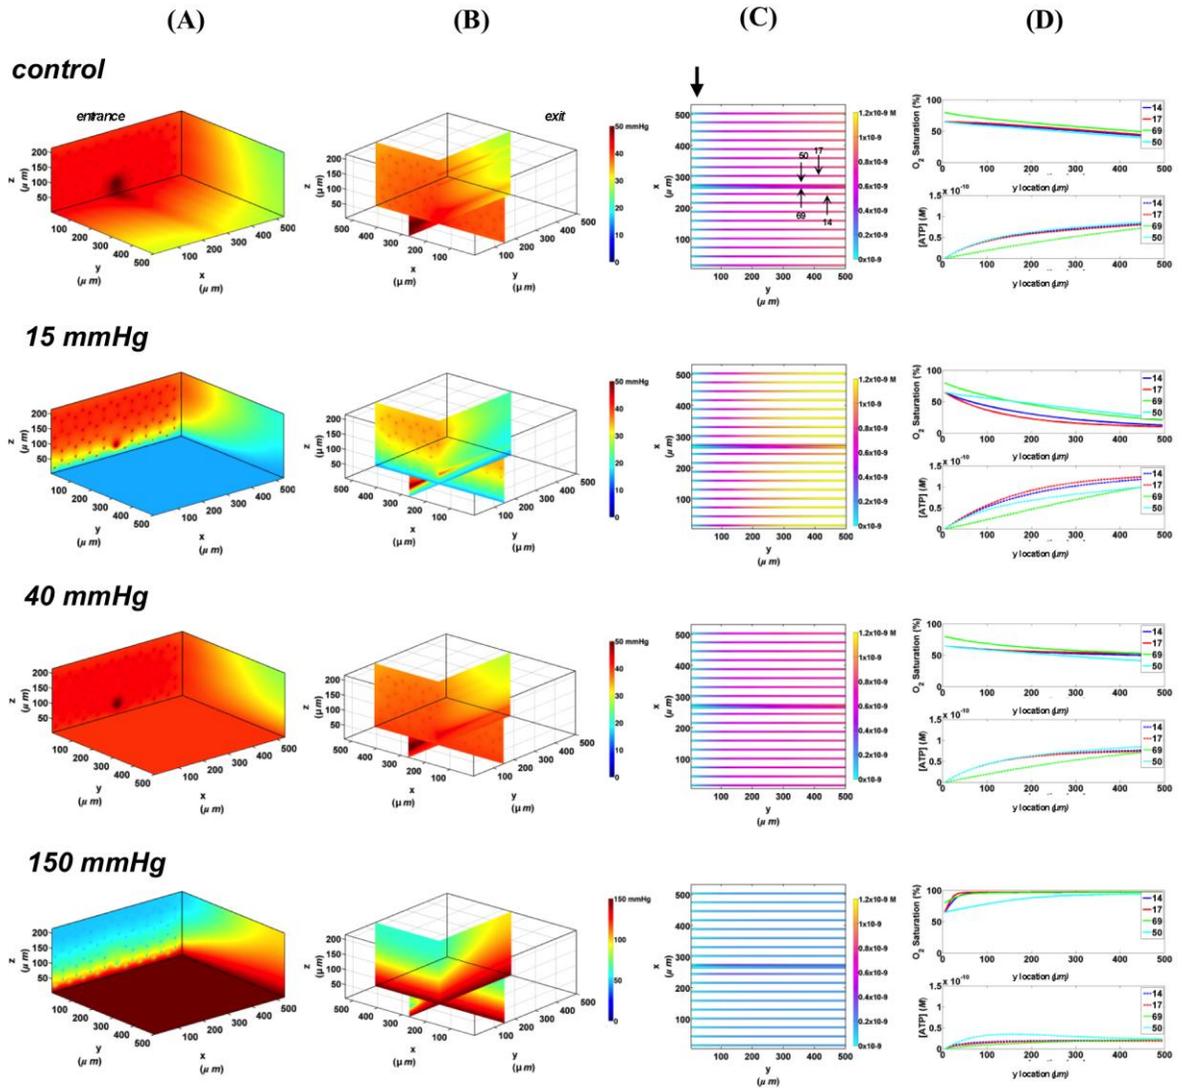

In the 3D tissue  $PO_2$  profiles and [ATP] vessel maps generated for these simulations, the  $PO_2$  perturbations were shown to affect the terminal arteriole to a much lesser extent than the surface capillaries (Figure 3.8A,B and 3.9A,B). Also, these simulations showed the influence of the arteriole as an  $O_2$  source on the  $SO_2$  levels of nearby surface capillaries. For instance, the steady state  $SO_2$  level in capillary 14, positioned right next to the arteriole, was ~25% higher than the zero flux control condition when exposed to 40 mmHg chamber  $PO_2$  and identical to the  $SO_2$  level of the terminal arteriole (Figure 3.8 and 3.9). However, the  $SO_2$  level of the deeper tissue capillary (50), which was located at the same depth as capillary 54, was unchanged relative to zero flux. In general, the different arteriolar entrance  $SO_2$  has no effect on the surface or deep tissue capillaries and had minimal influence on the arteriolar  $SO_2$  at steady state. At 15 mmHg, the  $SO_2$  level of the terminal arteriole entering at 65% dropped by 60% relative to zero flux condition corresponding to 44% increases in [ATP]. A smaller drop in  $SO_2$  was calculated (52% decrease) for the arteriole entering at 80% corresponding to 40% increase in [ATP]. The  $SO_2$  level in the surrounding surface capillaries, as well as deeper tissue capillaries, dropped by ~70% and 35%, respectively, corresponding to ~45% and 16% higher steady state capillary [ATP] relative to zero flux (Figure 3.8C and 3.9C). At 150 mmHg, hemoglobin  $SO_2$  levels in surface and deep tissue capillaries as well as in the arteriole converged to ~100% with ~77% decrease in steady state [ATP] in the capillaries and

75% decrease in [ATP] in the arteriole relative to zero flux control (Figure 3.8C and 3.9C).

**Figure 3.8** Simulations of 3D PO<sub>2</sub> and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (68 hexagonally packed capillaries), plus a traversing terminal arteriole (vessel 69) at an entrance SO<sub>2</sub> of 65%. In these simulations,

we are modeling O<sub>2</sub> delivery to the bottom tissue surface using the full gas exchange chamber (Ellis et al., 2012; Ghonaim et al., 2011). Full bottom tissue surface is exposed to 15 mmHg, 40 mmHg, or 150 mmHg chamber PO<sub>2</sub> level relative to a zero flux control boundary condition (A) Spatial 3D tissue PO<sub>2</sub> distribution (mmHg) at capillary entrance perspective (B) a capillary exit perspective showing combined X-Z plane slice at Y=150 μm and Y-Z plane slice at X= 266 μm (C) bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the arteriole and surrounding capillaries. Bolded arrow marks arteriolar and capillary entrance (D) Plots of SO<sub>2</sub> (%) and [ATP] changes along vessel length in selected vessels (14, 17, 69-arteriole, 50) marked by arrows on the vessel map. Capillary 17 is 16 μm from tissue surface, the arteriole and capillary 14 are 33 μm from tissue surface, and capillary 50 is deeper in the tissue, at 133 μm, yet is shown adjacent to the arteriole in the current perspective of the vessel map.

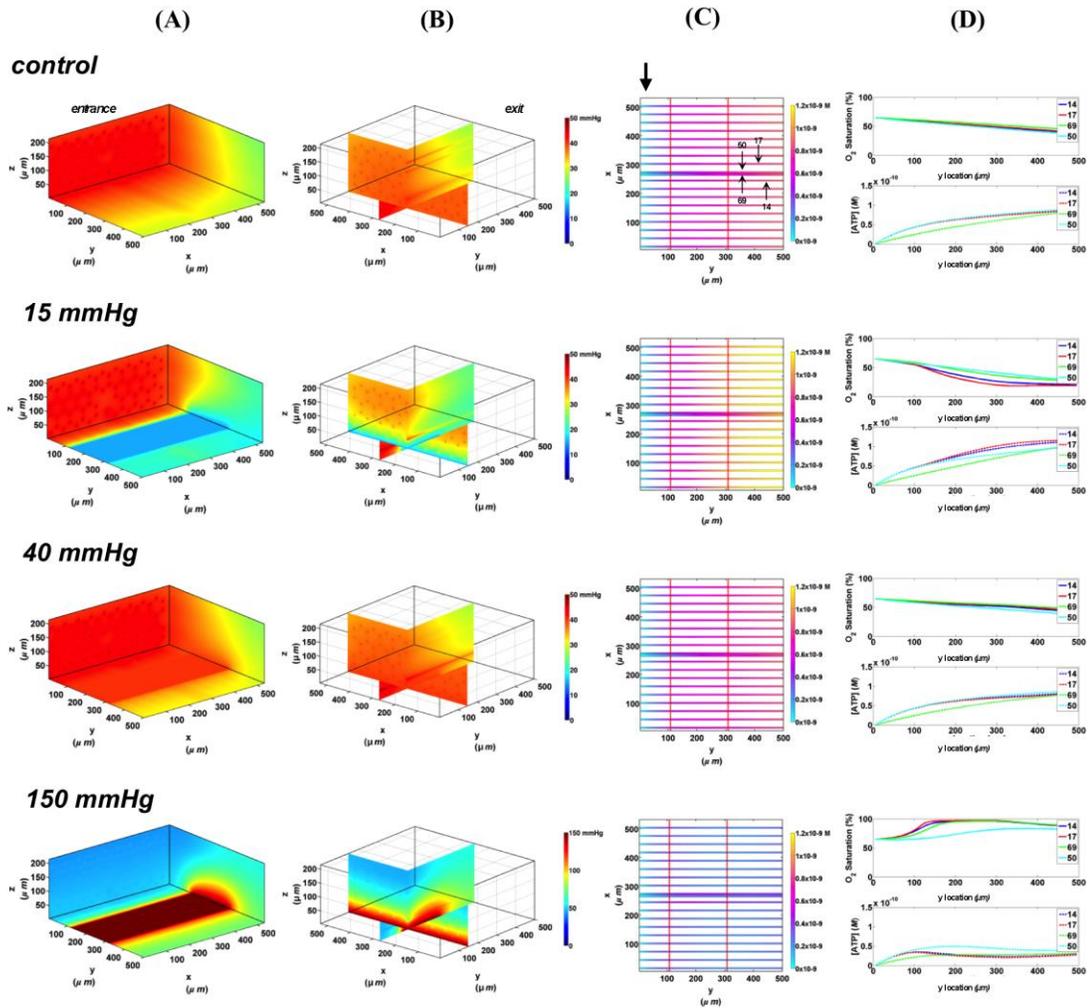

**Figure 3.9** Simulations of 3D  $PO_2$  and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (68 hexagonally packed capillaries), which includes a traversing terminal arteriole (vessel 69) at an entrance  $SO_2$  of 80%. In these simulations, we are modeling  $O_2$  delivery to bottom tissue surface using the full gas exchange chamber (Ellis et al., 2012; Ghonaim et al., 2011). Full bottom tissue surface is

exposed to 15 mmHg, 40 mmHg, or 150 mmHg chamber PO<sub>2</sub> level relative to a zero flux control boundary condition (A) Spatial 3D tissue PO<sub>2</sub> distribution (mmHg) at capillary entrance perspective (B) a capillary exit perspective showing combined X-Z plane slice at Y=150 μm and Y-Z plane slice at X= 266 μm (C) bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the arteriole and surrounding capillaries. Bolded arrow marks arteriolar and capillary entrance (D) Plots of SO<sub>2</sub> (%) and [ATP] changes along vessel length in selected vessels (14, 17, 69-arteriole, 50) marked by arrows on the vessel map. Capillary 17 is 16 μm from tissue surface, the arteriole and capillary 14 are 33 μm from tissue surface, and capillary 50 is deeper in the tissue, at 133 μm, yet is shown adjacent to the arteriole in the current perspective of the vessel map.

### **3.3.2.2 *Rectangular oxygen delivery micro-slit at 65% and 80% arteriolar entrance SO<sub>2</sub>***

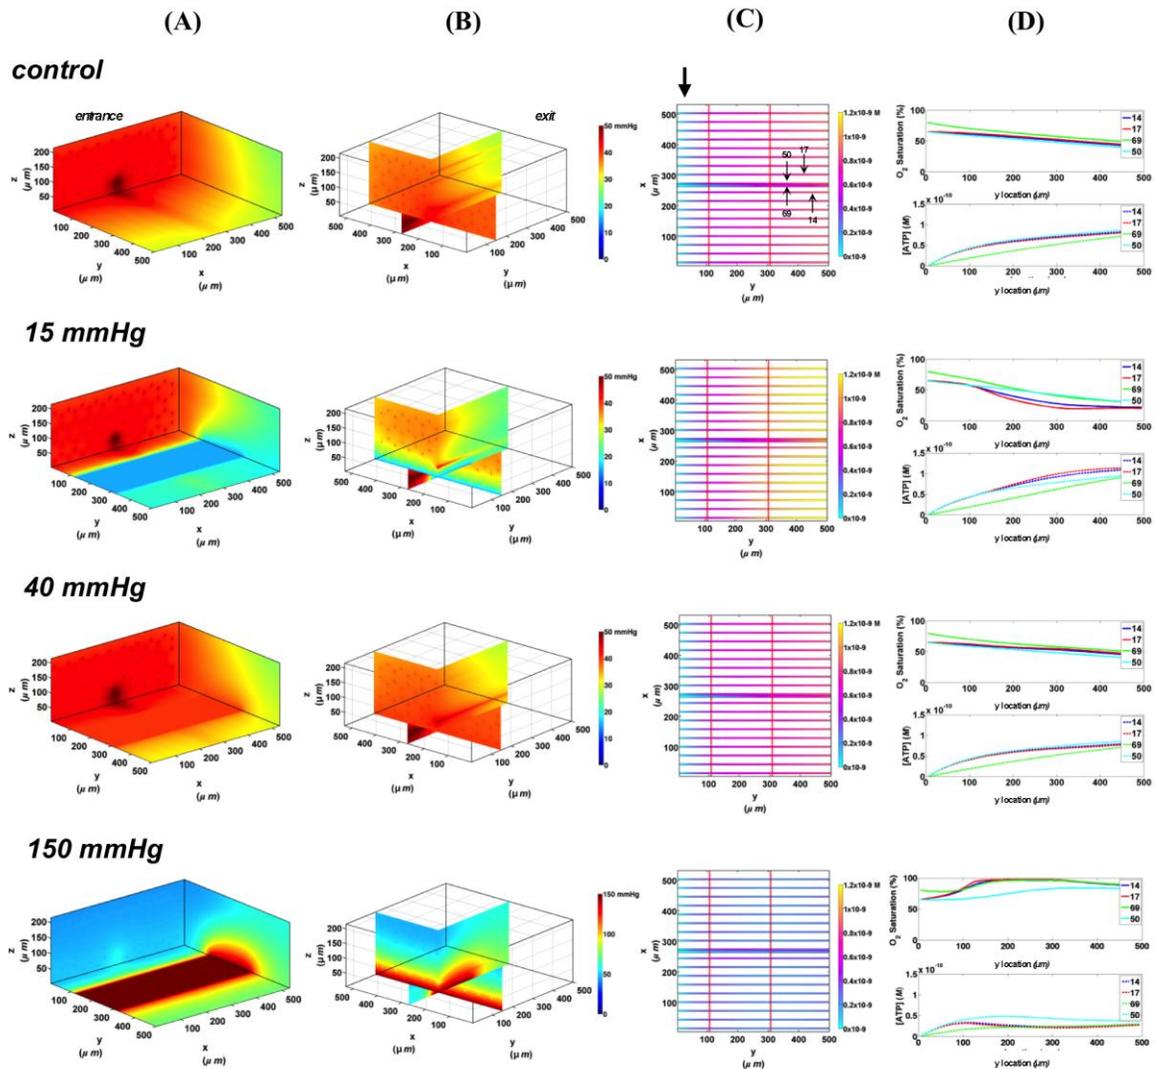

In these simulations, the capillary array that includes the terminal arteriole is exposed to local perturbations in tissue PO<sub>2</sub> through the rectangular micro-slit. At 40 mmHg chamber PO<sub>2</sub>, the calculated steady state SO<sub>2</sub> and [ATP] levels at the venular end of surface and deep tissue capillaries as well as in the arteriole are within 5% of those at zero flux condition and uninfluenced by the arteriolar entrance SO<sub>2</sub> (Figure 3.10 and 3.11). Under imposed hypoxia (15 mmHg), the calculated arteriolar SO<sub>2</sub> values at steady state were 50% higher than the case in which the full surface is exposed to the PO<sub>2</sub>

perturbations and identical to those of deeper tissue capillaries. Hence, a minimal drop in  $\text{SO}_2$  (38% decrease) was calculated in the arteriole relative to zero flux. These arteriolar steady state  $\text{SO}_2$  values were uninfluenced by the different arteriolar entrance  $\text{SO}_2$ . The influence of the arteriole as an  $\text{O}_2$  source to nearby capillaries downstream of the micro-slit can be clearly observed in the 3D  $\text{PO}_2$  profiles at 15 mmHg (Figure 3.10A and 3.11A). However, the surface capillaries (14, 17) experienced a sharper drop in  $\text{SO}_2$  in response to the imposed hypoxia with 53% drop in  $\text{SO}_2$  and a corresponding 39% increase in [ATP]. As observed when locally stimulating surface capillaries in the absence of the arteriole, capillaries were re-oxygenated  $\sim 40 \mu\text{m}$  downstream of the hypoxic micro-slit region. At 150 mmHg, the steady state  $\text{SO}_2$  levels in surface capillaries and in the arteriole converged to  $\sim 88\%$  while the  $\text{SO}_2$  level of capillary 50 was slightly lower at 83% which corresponded to 65% and 57% decrease in [ATP], respectively, relative to zero flux (Figure 3.10C and 3.11C).

**Figure 3.10** Simulations of 3D  $PO_2$  and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (68 hexagonally packed capillaries), which includes a traversing terminal arteriole (vessel 69) at an entrance  $SO_2$  of 65%. In these simulations, we are modeling  $O_2$  delivery through a rectangular oxygen micro-delivery outlet (1000  $\mu m$  wide x 200  $\mu m$  long) to bottom tissue surface using our previously described novel micro-delivery approach (see Figure 3.1). Tissue surface directly on top

of the micro-delivery outlet is exposed to 15 mmHg, 40 mmHg, or 150 mmHg chamber PO<sub>2</sub> level relative to a zero flux control boundary condition (A) Spatial 3D tissue PO<sub>2</sub> distribution (mmHg) at capillary entrance perspective (B) a capillary exit perspective showing combined X-Z plane slice at Y=150 μm and Y-Z plane slice at X= 266 μm (C) bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the arteriole and surrounding capillaries. Bolded arrow marks arteriolar and capillary entrance (D) Plots of SO<sub>2</sub> (%) and [ATP] changes along vessel length in selected vessels (14, 17, 69-arteriole, 50) marked by arrows on the vessel map. Capillary 17 is 16 μm from tissue surface, the arteriole and capillary 14 are 33 μm from tissue surface, and capillary 50 is deeper in the tissue, at 133 μm, yet is shown adjacent to the arteriole in the current perspective of the vessel map.

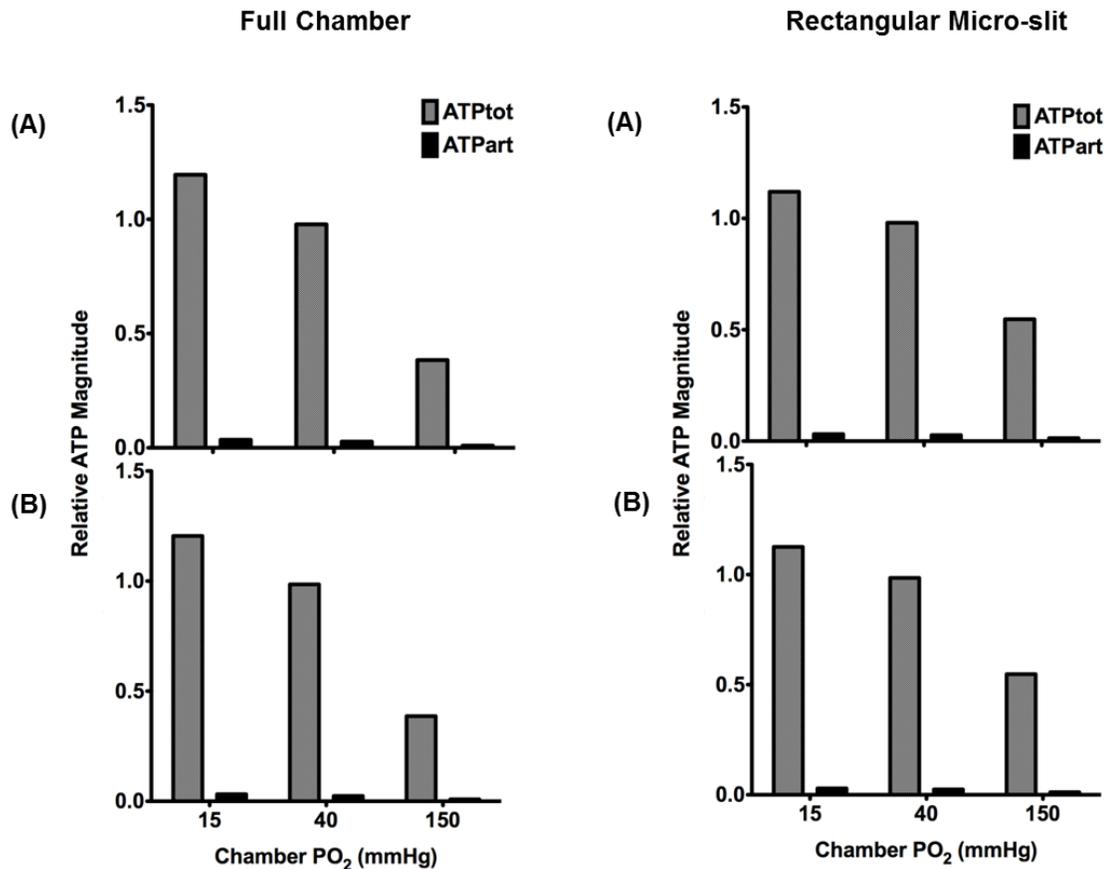

**Figure 3.11** Simulations of 3D  $PO_2$  and capillary [ATP] distribution in a tissue with idealized parallel capillary arrangement (68 hexagonally packed capillaries), which includes a traversing terminal arteriole (vessel 69) at an entrance  $SO_2$  of 80%. In these simulations, we are modeling  $O_2$  delivery through a rectangular oxygen micro-delivery outlet ( $1000 \mu m$  wide x  $200 \mu m$  long) to bottom tissue surface using our previously described novel micro-delivery approach (see Figure 3.1). Tissue surface directly on top

of the micro-delivery outlet is exposed to 15 mmHg, 40 mmHg, or 150 mmHg chamber  $PO_2$  level relative to a zero flux control boundary condition (A) Spatial 3D tissue  $PO_2$  distribution (mmHg) at capillary entrance perspective (B) a capillary exit perspective showing combined X-Z plane slice at  $Y=150\ \mu\text{m}$  and Y-Z plane slice at  $X=266\ \mu\text{m}$  (C) bottom perspective of a vessel map depicting distribution of [ATP] (mol/L=M) along the arteriole and surrounding capillaries. Bolded arrow marks arteriolar and capillary entrance (D) Plots of  $SO_2$  (%) and [ATP] changes along vessel length in selected vessels (14, 17, 69-arteriole, 50) marked by arrows on the vessel map. Capillary 17 is  $16\ \mu\text{m}$  from tissue surface, the arteriole and capillary 14 are  $33\ \mu\text{m}$  from tissue surface, and capillary 50 is deeper in the tissue, at  $133\ \mu\text{m}$ , yet is shown adjacent to the arteriole in the current perspective of the vessel map.

### **3.3.2.3 *Estimating relative arteriolar ATP magnitude in response to tissue $PO_2$ perturbations***

In order to estimate the contribution of the terminal arteriole to ATP mediated signaling in capillary networks, the steady state magnitude of ATP in the arteriole ( $ATP_{\text{art}}$ ) at various tissue  $PO_2$  conditions was calculated and normalized against total ATP magnitude in the network ( $ATP_{\text{tot}}$ ) under zero flux condition (Figure 3.12). The relative arteriolar ATP magnitudes were calculated when the full tissue surface was exposed to the  $PO_2$  perturbations (full gas exchange chamber) or to local perturbations using the rectangular  $O_2$  delivery micro-slit. As shown in Figure 3.12, the arteriolar ATP

magnitude decreased with increase in chamber  $PO_2$  level. However, the model suggested that under hypoxic conditions (15 mmHg), the terminal arteriole would contribute less than 3% of the total ATP signal originating from a capillary network. Also, although the percent decrease in ATP magnitude in the arteriole is similar to that calculated for the total network when increasing chamber  $PO_2$  from 15 mmHg to 150 mmHg, the absolute change in ATP magnitude (moles) in the arteriole is ~95% less. Finally, it should be noted that [ATP] in the arteriole is ~20% lower when limiting area of  $PO_2$  perturbations using the rectangular micro-slit.

**Figure 3.12** Total ATP magnitude (moles) at steady state calculated for entire network (ATPtot from all 68 capillaries) or in the terminal arteriole only (ATPPart) normalized against ATPtot calculated at no-flux condition. Relative ATP magnitudes are calculated for an idealized 3D parallel capillary array network with a terminal arteriole (9  $\mu\text{m}$  in diameter) positioned 30  $\mu\text{m}$  from tissue surface. Simulations were run with entire bottom tissue surface being exposed to  $PO_2$  perturbations using full gas exchange chamber or locally using a rectangular  $O_2$  delivery micro-slit (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long). For both conditions, relative ATP magnitudes are calculated for the case in which the terminal arteriole has an entrance  $SO_2$  of (A) 65% or (B) 80%.

### 3.4 Discussion

In the microcirculation, ATP is released from the erythrocytes in an  $\text{SO}_2$  dependent manner. Released ATP would bind to purinergic receptors on the vascular endothelium which activates a signaling pathway leading to the opening of  $\text{Ca}^{2+}$  gated  $\text{K}^+$  channels and the hyperpolarization of the endothelial cell (Ellsworth et al., 2008, Tran et al., 2012). The hyperpolarization signal is then conducted upstream through gap junctions. At the arteriolar wall, the incoming hyperpolarization signal is conducted to the SMC layer through myo-endothelial gap junctions resulting in vaso-relaxation and increase in erythrocyte supply rate (Ellsworth et al., 2008, Tran et al., 2012). The magnitude of the hyperpolarization signal would depend on the number of endothelial cells activated along the capillary and on the total number of capillaries stimulated within a network under hypoxic conditions. This understanding of how erythrocyte-released ATP controls micro-vascular  $\text{O}_2$  delivery is consistent with the modeling results presented in this paper. The net increase in total ATP magnitude in the network with increase in the area exposed to hypoxia is the summative contribution of additional stimulated capillaries (Figures 3.3-3.7). Also, these results help explain our observations of no associated vascular response to changes in capillary  $\text{SO}_2$  when experimentally testing the effect of  $\text{O}_2$  delivery through a circular micro-outlet (100  $\mu\text{m}$  in diameter) *in vivo* (Ghonaim et al., 2011). Although this design maybe optimal for locally altering  $\text{SO}_2$  in single capillaries, the stimulus would probably not be sufficient to elicit a micro-vascular response. Increasing the dimensions

of the micro-outlet would be necessary to stimulate a large enough number of capillaries, thus amplifying total magnitude of ATP release and signal.

Also, as our modeling data suggest, increasing the micro-outlet dimensions minimizes the effect of stimulated capillary re-oxygenation downstream of the micro-outlet. This is because the capillaries of interest would be surrounded by capillaries experiencing the same drop in  $PO_2$ . This is more representative of the situation *in vivo* as the outlet physiologically simulates an arteriole crossing the capillary bed acting as an  $O_2$  source or a venule withdrawing  $O_2$ , which would affect multiple capillaries. In terms of the signaling response, delayed re-oxygenation following hypoxic stimulation ensures the ATP signal persists longer distances downstream thus stimulating a larger number of endothelial cells. Since each endothelial cell in skeletal muscle is  $\sim 100 \mu\text{m}$  long, using the rectangular slit is estimated to activate at least 3.5 endothelial cells in each stimulated capillary. In comparison with the square micro-outlet, which has the same length ( $200 \mu\text{m}$ ) as the rectangular micro-slit, approximately one more endothelial cell is activated per capillary with the latter design. It should be noted that in the modeled geometry, which lacks realistic capillary branching and has an idealized, uniform capillary density, we are examining relative changes in the total magnitude of ATP when using various outlet designs. During *in vivo* experiments, a maximum of two micro-vascular units ( $\sim 10$  capillaries) may be positioned along the entire width of the rectangular micro-slit, while only one or two capillaries with a branching point could be positioned over the circular micro-outlet (Ghonaim et al., 2011). Hence a  $1000 \mu\text{m}$  wide x  $200 \mu\text{m}$  long outlet might

cover the threshold number of capillaries needed to elicit a micro-vascular response. This indicates the rectangular micro-slit would be optimal for affecting a sufficient number of capillaries by local O<sub>2</sub> perturbations to generate a sufficient ATP signal for eliciting a conducted micro vascular response.

The limited amount of change in tissue PO<sub>2</sub> due to diffusion (~50 μm), as measured from the 3D tissue PO<sub>2</sub> profiles, beyond the edge of the micro-outlets (Figures 3.4-3.6A,B) was consistent with our previous observations (Ghonaim et al., 2011). The simulations indicated that the PO<sub>2</sub> perturbations are highly localized to only those capillaries directly over the micro-outlet region. Experimentally, the results suggest that the micro-outlet should be positioned at least 50 μm downstream of the terminal feeding arteriole to ensure that micro-vascular responses are only elicited from the capillaries positioned directly over the outlet. The extent of axial O<sub>2</sub> diffusion in the tissue when using the rectangular micro-slit was 50% deeper than that previously modeled for the circular micro-outlet (Figure 6B, 10B, 11B) (Ghonaim et al., 2011) and similar to that of the full surface model (Ellis et al., 2012, Ghonaim et al., 2011). Due to the shape of the PO<sub>2</sub> profile, the maximal axial diffusion distance was estimated from the center of the outlet. The increase in the axial diffusion distance might be a compromise when using larger O<sub>2</sub> micro-outlets. With our current microscopic techniques we are unable to resolve vessels deeper than 60 μm.

Since in our experiments, we examine micro-vascular signaling from selected capillaries, it was critical that we assess the possible contribution of arterioles beyond our ability to

focus. Since arterioles have relatively higher erythrocyte velocities than in the capillaries, they are anticipated to experience a much lesser change in  $SO_2$  in response to  $PO_2$  perturbations. This was supported by our simulation data (Figure 3.8-3.11). The main effect of a nearby terminal arteriole on a capillary within  $50\ \mu\text{m}$  is that it would act as an  $O_2$  source. As shown in our modeling data (Figure 3.8-3.11D), higher measured  $SO_2$  in a capillary relative to other capillaries with comparable flow rates in the same preparation might imply the presence of a nearby arteriole. Since arterioles in the EDL muscle preparation are deeper in the tissue, their contribution to the total magnitude of ATP in a locally stimulated capillary network is probably negligible. The contribution of a terminal arteriole positioned directly over the micro-slit  $\sim 30\ \mu\text{m}$  from the bottom surface was calculated to be less than 3% of the total magnitude of the ATP (Figure 3.12). Hence, when locally stimulating capillaries, even in the presence of an underlying arteriole, the observed micro-vascular responses mediated by intra-luminal ATP would be primarily due to ATP released in the stimulated capillaries.

In conclusion, we have modeled  $SO_2$ -dependent changes in [ATP] at steady state in 3D idealized parallel capillary networks in response to local  $PO_2$  perturbations. As the number of affected capillaries increases, the total magnitude of ATP in the network increases. The results indicated that  $O_2$  delivery or removal to overlaying tissue through a rectangular micro-slit ( $1000\ \mu\text{m}$  wide x  $200\ \mu\text{m}$  long) would be optimal relative to other micro-outlet designs of smaller dimensions or a full surface classical exchange type chamber. Using the rectangular micro-slit it is anticipated that a sufficient number of

capillaries will be stimulated to produce sufficient ATP to elicit micro-vascular responses. This would be accomplished while maintaining the stimulus localized to the selected capillaries. The results also indicated that terminal arterioles have minimal influence on the total magnitude of ATP in the network under hypoxic condition. Hence, when locally stimulating the capillary bed, the majority of the signal elicited by ATP release would originate in the capillaries. The computational model presented provides valuable insights into how to study the ATP release mechanism and signaling in capillary networks *in vivo*. The modeling data help guide us in the design of an optimal tool for studying  $\text{SO}_2$ -dependent ATP release in capillaries *in vivo*. In the future, we aim to model time-dependent ATP release to local  $\text{PO}_2$  perturbations in a realistic capillary network geometry reconstructed from experimental data. Combining our *in vivo* experimental observations with computational modeling of the dynamics of  $\text{SO}_2$ -dependent ATP release will help provide a more comprehensive understanding of  $\text{O}_2$  mediated blood flow regulation in micro-vascular networks.

## Chapter 4

### **4 Conducted microvascular response to localized oxygen exchange using a novel micro-delivery approach<sup>1</sup>**

<sup>1</sup> In preparation for submission to *Circulation Research* (2013).

#### **4.1 Introduction**

For a long time, micro-vascular responses to changes in the oxygen ( $O_2$ ) environment have been observed as changes in vascular tone (Duling and Berne 1970, Jackson and Duling 1983, Jackson 1987). This observation has been exploited in experiments involving the use of suffusion solutions as a standard procedure for testing the viability of the tissue preparation (Jackson et al. 2010). In a healthy tissue, increasing  $O_2$  levels of the suffusion solution would result in arteriolar vasoconstriction and consequent flow reduction. Equilibrating the suffusion solution back at near zero  $O_2$  levels would result in an observed increase in flow that would recover normal perfusion. The finding that  $O_2$  content (proportional to hemoglobin  $O_2$  saturation;  $SO_2$ ) is more important than  $O_2$  partial pressure ( $PO_2$ ) in generating a micro-vascular response (Stein et al. 1993) suggested the erythrocyte maybe actively involved in mediating the observed  $O_2$ -dependent flow responses. The ability of the erythrocyte to release signaling molecules that act to modulate blood flow in response to drop in internal hemoglobin  $SO_2$  (Stein et al. 1993, Ellsworth et al. 1995) further confirmed the erythrocyte's proposed role as a mobile vascular  $O_2$  sensor and effector. Of special interest is the potent vasodilator adenosine

triphosphate (ATP), which was found to be released by erythrocytes under low  $\text{SO}_2$  conditions (Ellsworth et al. 1995). Jagger et al. (2001) demonstrated that the relationship between ATP release from the erythrocyte and hemoglobin  $\text{SO}_2$  is linear. The mechanisms that underlay  $\text{SO}_2$ -dependent ATP release by the erythrocyte are not fully elucidated, but are suggested to involve conformational changes in the hemoglobin molecule as it desaturates (Jagger et al. 2001, Wan et al. 2008; Sridharan et al. 2010b; Forsyth et al. 2011) which activates signalling pathways similar to those involved in shear stress dependent ATP release (Sprague et al. 1998; 2001; 2008). Once ATP is released, it binds to purinergic receptors ( $\text{P}_{2y}$ ) on the vascular endothelium (You et al. 1999, Horiuchi et al. 2001) leading to conducted hyperpolarization between adjacent endothelial cells through gap junctions and to smooth muscle cells (SMCs) through myoendothelial cell junctions (Campbell et al. 1996, Dietrich et al. 2008, Fukao et al. 2001).

Activation of SMCs leads to local and conducted vasodilation up the arteriolar tree which translates to increase in perfusion (Segal et al. 1989, Segal and Duling 1989). It has been suggested that other vasodilators such as SNOs and nitric oxide (NO) may be released from the erythrocyte under low  $\text{SO}_2$  (Jia et al. 1996, Stamler et al. 1997, Patel et al. 1999, Cosby et al. 2003, Gladwin et al. 2004). However, the physiological role of SNOs *in vivo* is still to be identified (Ellsworth et al. 2009). Also, the suggested mechanisms lack the temporal resolution required to rapidly control  $\text{O}_2$  distribution and although implicated in

local vasodilation, these mechanism have not been shown to result in conducted microvascular signaling (Ellsworth et al. 2009).

There is a lot of debate as to the site of ATP release and action in the microvasculature. It has been suggested that ATP would primarily be released in terminal arterioles such that it would directly activate SMCs resulting in prompt responses (Duling and Berne, 1970, Duling, 1974, Jackson, 1987). However, the spatial resolution of the microvascular signal in the arterioles would be highly compromised by the relatively short erythrocyte transit times (Ellis et al. 2012). Also, the parabolic flow profile implies that only cells nearest the wall will experience the drop in  $SO_2$  and thus contribute in the release of ATP. Cells flowing in the center line would experience the  $SO_2$  drop to a much lesser extent and any released ATP would need to diffuse a long distance prior to acting on the endothelium (Ellis et al. 2012).

Studies have shown that ATP injected into the vascular lumen of venules would result in a signal conducted to the upstream arterioles (Collins et al. 1998). The high level of hematocrit collected in the venules, combined with low  $SO_2$  levels, results in large amounts of released ATP (Ellis et al. 2012). Hence venules would be the site for strong vasodilatory signals (Arciero et al. 2008). However, since venules collect erythrocytes with a wide range of  $SO_2$  values from upstream capillaries, signals originating from the venules would contribute to regional blood flow regulation rather than to control the distribution of blood supply to specific capillary beds (Ellis et al. 2012).

In order for the O<sub>2</sub> regulatory system to maintain a homogenous O<sub>2</sub> supply across the capillary bed, the O<sub>2</sub> regulatory signal has to originate within the capillary itself to ensure proper distribution of O<sub>2</sub> supply to match the dynamic changes in capillary SO<sub>2</sub> (Ellis et al 2012). The relatively longer erythrocyte transit times in the capillaries and the small diffusion distance of ATP to the endothelium from every passing erythrocyte imply that the capillary bed could be the site for effective SO<sub>2</sub>-dependent ATP signaling (Ellis et al 2012). Since capillaries are composed of endothelial cells which are electrically coupled (Dietrich, 1989, Dietrich and Tyml, 1992a,b, Song and Tyml, 1993, Collins et al., 1998, Bagher and Segal, 2011), signal can be conducted to the upstream arteriole in the same way that it was conducted from the downstream venule (Collins et al. 1998). Signals integrated from capillaries in nearby yet independent microvascular units would lead to more tightly controlled responses.

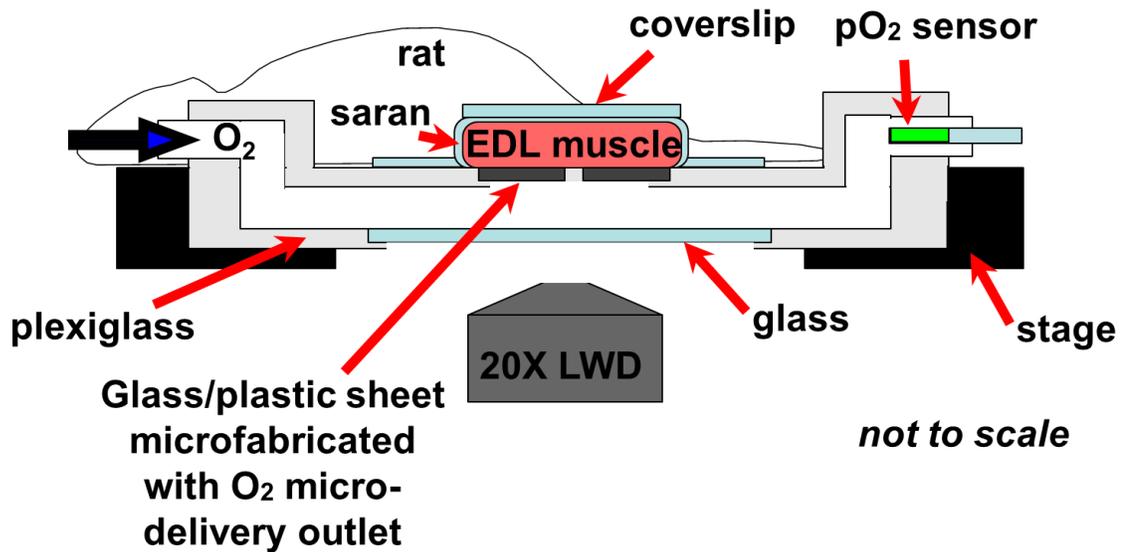

One of the factors that contribute to the heterogeneity in capillary SO<sub>2</sub> is the observed cross talk between microvessels within the complex microvascular geometry (Swain and Pittman 1989, Ellsworth and Pittman 1990, Stein et al. 1993, Ellsworth et al. 1994, Tsai et al. 2003). An arteriole crossing over a group of capillaries will act as a diffusion shunt increasing O<sub>2</sub> content in the affected capillaries. On the other hand, a crossing venule would act to remove O<sub>2</sub> from the capillaries thus decreasing their erythrocyte SO<sub>2</sub> level (Ellis et al. 2012). This implies that under normal physiological conditions, and in the absence of changes in metabolic demand, there is heterogeneity in capillary SO<sub>2</sub> levels partially attributed to variations in the surrounding microvascular geometry and

environment. The heterogeneity in capillary  $SO_2$  could also be due to the uneven erythrocyte distribution at upstream arteriolar branch points. In the arterioles, cells nearest the wall will have lower  $SO_2$  than in the centerline (Ellsworth and Pittman 1986, Carvalho and Pittman 2008). Plasma skimming will result in downstream capillaries receiving different populations of erythrocytes at different  $SO_2$  levels (Tyml et al. 1981, Ellis et al. 1994, Pries et al. 1996).

In order to investigate micro-vascular response to local tissue  $PO_2$  perturbations, we have developed a micro-delivery system which allows for altering the erythrocyte  $SO_2$  in selected capillaries in response to local tissue  $PO_2$  changes (Ghonaim et al. 2011) (Figure 4.1). In this setup,  $O_2$  from a gas mixture flowing through the micro-delivery system is exchanged with tissue (rat Extensor Digitorum Longus) positioned directly above an  $O_2$  micro-outlet microfabricated in ultrathin glass/plastic. The micro-delivery system is used in conjunction with *in vivo* video microscopy (IVVM) system which allows for recording blood flow responses while simultaneously controlling erythrocyte  $SO_2$  in selected capillaries (Ellis et al. 2010; 2012). Theoretical modeling and *in vivo* testing with a circular micro-outlet (100  $\mu\text{m}$  in diameter) confirmed that erythrocyte  $SO_2$  can be altered and measured in single capillaries flowing over a micro-outlet with the above dimensions (Ghonaim et al. 2011) and that the effect is restricted to the immediate area of the micro-outlet. Further modelling work (Ghonaim et al. 2013) indicated that the total magnitude of ATP in the network is proportional to the number of affected capillaries. The results suggested that with a rectangular micro-slit design (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long) a

sufficient number of capillaries are stimulated to produce sufficient ATP signal while limiting the area of perturbation to the immediate vicinity of the micro-slit.

In this study, we aimed to investigate conducted  $\text{SO}_2$ -dependent microvascular responses in the capillary bed using the  $\text{O}_2$  micro-delivery system. We hypothesize that capillaries are able to signal upstream arterioles for changes in erythrocyte supply rate in response to changes in capillary  $\text{SO}_2$  via  $\text{SO}_2$ -dependent erythrocyte signaling. The rectangular micro-slit design previously modeled for  $\text{O}_2$  exchange was tested *in vivo* (Figure 4.2B). Our results indicated that capillaries are able to regulate the distribution of arteriolar blood flow in response to changes in their erythrocyte  $\text{SO}_2$ . Also, in support with our modeling data (Ghonaim et al. 2013), there appears to be a threshold for the minimum number of capillaries that need to be stimulated by altered  $\text{SO}_2$  in order to induce a conducted microvascular response. Although erythrocyte  $\text{SO}_2$  can be measured in single capillaries flowing over an  $\text{O}_2$  micro-outlet window down to 100  $\mu\text{m}$  in diameter, at least 3-4 capillaries need to be stimulated within a branching capillary network in order to induce a microvascular response. The variability in the minimum number of capillaries that need to be stimulated is likely dependent on the number of capillaries supplied by a specific branch of the arteriolar tree. Microvascular responses originate from a capillary network positioned directly over the outlet with the terminal end of the feeding arteriolar end positioned  $>50$   $\mu\text{m}$  upstream from the micro-outlet, which suggests the signal was conducted upstream from the site of stimulation. These results support the hypothesis that capillaries can sense and integrate biological responses.

**Figure 4.1** The O<sub>2</sub> micro-delivery system. Extensor Digitorum Longus (EDL) rat muscle is surgically exposed and positioned on the viewing platform of an inverted microscope. O<sub>2</sub> is delivered to the surface of the muscle through a micro-delivery outlet patterned in ultrathin glass/plastic sheet. O<sub>2</sub> levels in the gas exchange chamber near the muscle surface are oscillated using computer controlled flow meters. Real-time videos of the illuminated tissue are monitored and recorded using a digital camera (Ellis et al. 2010, Ghonaim et al. 2011).

## **4.2 Materials and Methods**

### **4.2.1 Microfabrication**

Ultrathin glass/plastic sheets were patterned with the O<sub>2</sub> delivery micro-outlets using state-of-the art microfabrication techniques. The O<sub>2</sub> delivery micro-outlet is positioned directly beneath selected capillaries in the microvascular bed at the surface of the EDL muscle with the aid of an inverted microscope. The micro-outlets are covered with a Polydimethylsiloxane (*PDMS*) O<sub>2</sub> permeable layer to prevent fluid leakage into the device and direct exposure of the tissue to gas in the exchange chamber. The area of the microvascular bed, and hence the number of capillaries, that is stimulated is proportional to the area of the O<sub>2</sub> delivery micro-outlet. O<sub>2</sub> levels in the gas exchange chamber near the muscle surface are oscillated using computer-controlled flow meters, and O<sub>2</sub> is delivered to the tissue through the patterned outlets (Figure 4.1). Real-time videos of the illuminated tissue are monitored and recorded using a digital camera.

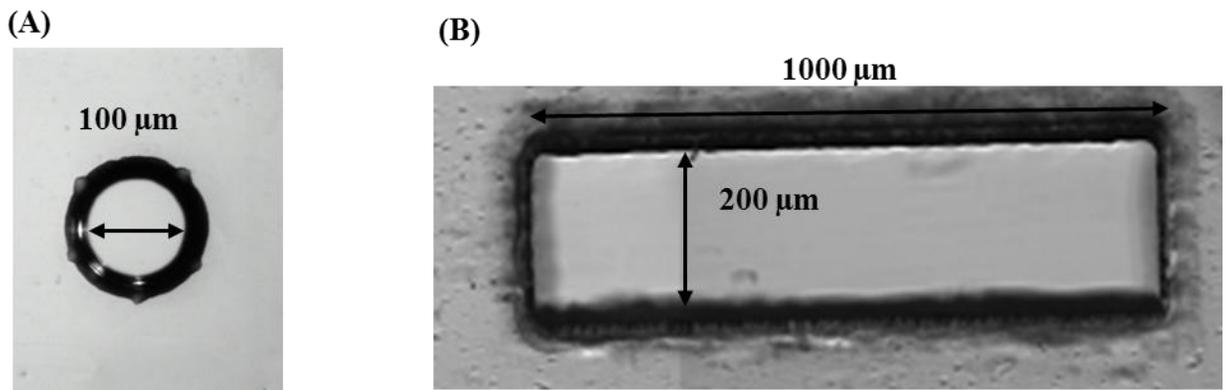

#### **4.2.1.1 *Patterning ultrathin glass***

The O<sub>2</sub> exchange circular micro-outlet (100 μm in diameter) was patterned in 30 μm thick D263C borosilicate glass substrate (SCHOTT North America, Inc., Elmsford, NY, USA), respectively, by photolithography and subsequent wet etching in hydrogen fluoride (Figure 4.2A). The photolithography and wet etching steps were carried out similar to previously described procedures (Ilie et al. 2003, Srivastava et al. 2005). Since the etching is isotropic, there is a certain degree of undercutting beneath the masking

layers (Ilie et al. 2003). This results in the pattern to be larger on the glass relative to the photomask. All pattern dimensions were optically measured at the top glass surface (glass surface directly beneath the masking layers) using QCapture Pro™ 6.0 software (QImaging®, Surrey, BC, Canada).

#### **4.2.1.2 Patterning poly-methyl methacrylate (PMMA) sheet**

The O<sub>2</sub> exchange micro-slit (1000 μm wide x 200 μm long) was patterned in 130 μm thick poly-methyl methacrylate (PMMA) substrate (Astra Products, Inc., Baldwin, NY, USA) by laser micromachining (Figure 4.2B).

**Figure 4.2** The O<sub>2</sub> delivery micro-outlets (A) A circular O<sub>2</sub> delivery micro-outlet 100 μm in diameter patterned in D263Tborosilicate ultrathin glass substrate (SCHOTT North America, Inc., Elmsford, NY, USA) as it appears under an upright light microscope at 10x objective. (B) A 200 μm long x 1000 μm wide rectangular O<sub>2</sub> delivery micro-slit patterned in poly-methyl methacrylate (PMMA) substrate (Astra Products, Inc., Baldwin, NY, USA) by laser micromachining as it appears under an inverted light microscope at 5x objective.

## **4.2.2 *In Vivo* Video Microscopy**

Erythrocyte  $\text{SO}_2$  and supply rates were measured in response to  $\text{O}_2$  exchange through the micro-outlets/micro-slits using IVVM techniques. Microvascular conducted responses result in changes in the erythrocyte supply rate due to changes in resistance in the upstream arteriolar tree. By varying the area of  $\text{O}_2$  exchange and hence the number of capillaries stimulated on the microvascular bed, the relationship between the onset of conducted microvascular response to low  $\text{PO}_2$  and the number of capillaries stimulated could be investigated.

Experiments using the 100  $\mu\text{m}$  diameter circular outlet were performed on a Nikon inverted microscope. Experiments using the 200  $\mu\text{m}$  long x 1000  $\mu\text{m}$  wide rectangular  $\text{O}_2$  delivery micro-slit were performed on a newer Olympus inverted microscope system with digital video cameras.

### **4.2.2.1 *Animal preparation***

All procedures described are approved from the University of Western Ontario's Animal Care and Use Committee. Five male Sprague-Dawley rats (Charles River Laboratories, Wilmington, MA, USA) (150-200 g) were anesthetized with pentobarbital sodium (6.5 mg/100 g body wt IP) and were subjected to a preparatory surgery as described (Ellis et al. 2002; 2010). The animals were mechanically ventilated at 30%  $\text{O}_2$  (70% Nitrogen), and the inspired  $\text{O}_2$  level (Oxychek) and blood pressure (MicroMed) were constantly monitored and recorded (Ellis et al. 2010). The Extensor Digitorum Longus (EDL)

muscle of the hind limb was identified and prepared for *in vivo* video microscopy as described by Tyml and Budreau (1991). The distal end of the EDL muscle was tied with a suture and the distal tendon cut. The muscle was extended along the viewing platform of either a Nikon inverted microscope equipped with long-working distance 10X and 20X objectives and a beam splitter for dual video cameras (DAGE-MTI CCD cameras, DAGE-MTI, Michigan City, IN, USA) or an Olympus IX-81 inverted microscope with 10 X and long working distance 20X objectives and DualCam beamsplitter with dual 12bit digital video cameras (Rolera XR cooled CCD). A suture attached to the distal end of the muscle was taped to the platform such that the muscle was stretched to its *in vivo* length. The muscle was covered with Saran Wrap (Dow Corning, Midland, MI, USA) and a cover slip to isolate it from room air and to preserve moisture. The tissue was trans-illuminated with either a 100-W xenon lamp on the Nikon microscope or a 75-W xenon lamp on the Olympus and viewed using the dual video camera system as described (Ellis et al. 2010).

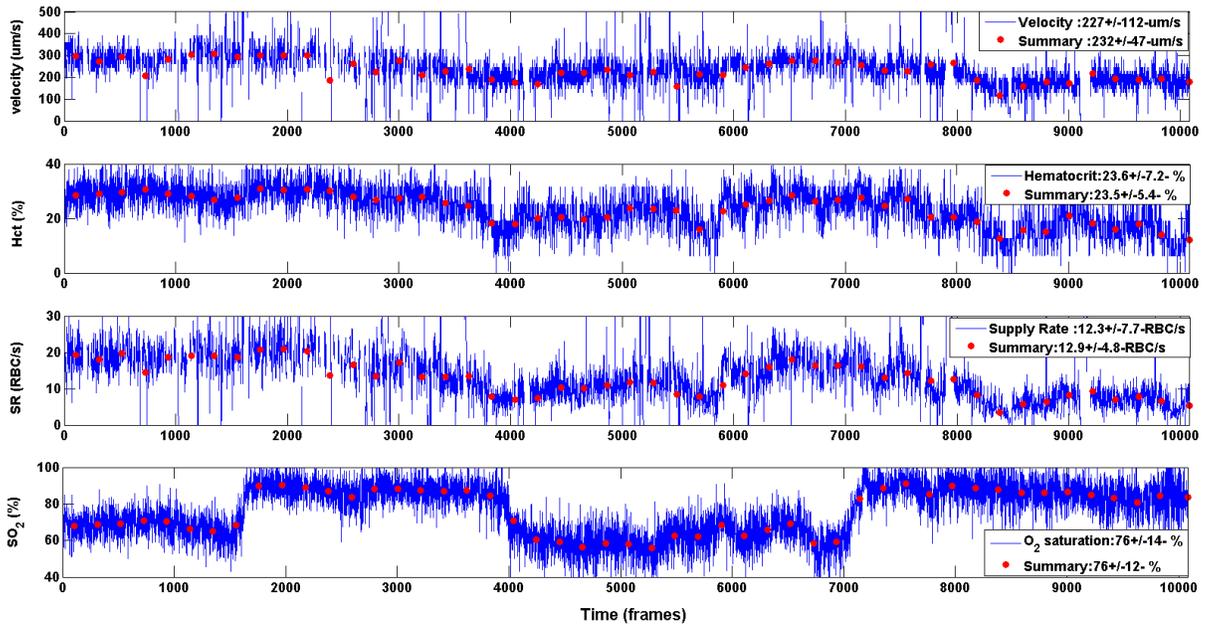

#### **4.2.2.2 *Dual wavelength intravital video microscopy system***

##### **D $\lambda$ IVVM**

Real-time video recordings (Nikon system: 640 x 480, 30 frames/second, 8 bit gray scale; Olympus: 696 x 520, 20.7 frames/second, 12 bit gray scale) of red blood cell (RBC) flow through capillaries were simultaneously obtained at two wavelengths, 431/442 nm, an O<sub>2</sub> sensitive wavelength for hemoglobin, and 420/454 nm, an isosbestic or O<sub>2</sub> insensitive wavelength (Ellsworth et al. 1987) using the dual video camera IVVM system (Ellis et al.

2010). Live video sequences from the DAGE-MTI CCD cameras on the Nikon were digitized using a DT frame grab board and stored as uncompressed 8 bit AVI movie files using custom acquisition software from Neovision (Ellis et al. 2010) for post-processing. Live digital video sequences were streamed from the Rolera XR cameras on the Olympus to the computer and stored as 16 bit uncompressed PNG files. Geometric, spatiotemporal, and photometric off-line analyses of the video sequences were conducted as described by Ellis et al. (Ellis et al. 1990; 1992) and Japee et al. (Japee et al. 2004; 2005) using algorithms written in MATLAB (Mathworks, Natick, MA) to generate functional images of the capillary network and to quantify changes in capillary hemodynamic parameters and erythrocyte  $SO_2$ .

In this study, either variance or sum of the absolute differences (SAD) functional images were used to illustrate the capillaries selected for analysis and surrounding geometry in an area of interest. In the variance image, areas with high temporal variation in light intensity (e.g. due to frequent passage of RBCs and plasma) will appear brighter, making capillaries more visible (Japee et al. 2004). In the SAD images, the sign of the variance is ignored, making the capillaries appear even brighter. Frame-by-frame measurements of hemodynamic parameters including RBC velocity ( $\mu\text{m}/\text{sec}$ ), supply rate (RBC/sec), hematocrit (%), and RBC  $SO_2$  (%) were conducted (30 frames/sec on the Nikon, 20.7 frames/sec on the Olympus) (Ellis et al. 1990; 1992, Japee et al. 2004; 2005) (Also see Figure 4.3). In all subsequent figures presented in this study, the data points were plotted as 10 sec averages for increased clarity.

**Figure 4.3** Frame-by-frame change in RBC velocity ( $\mu\text{m}/\text{sec}$ ), RBC hematocrit (% Hct), RBC supply rate (SR), and RBC  $\text{SO}_2$  (%). An eight minute (10,080 frames  $\times$  2) video sequence was captured using a dual wavelength video microscopy system, and post-processed for changes in various hemodynamic parameters using algorithms written in MATLAB (Mathworks, Natick, MA) as described by Ellis et al. (Ellis et al. 1990; 1992) and Japee et al. (Japee et al. 2004; 2005)

## **4.3 Results**

### **4.3.1 Examining the dependence of microvascular response on the number of capillaries stimulated**

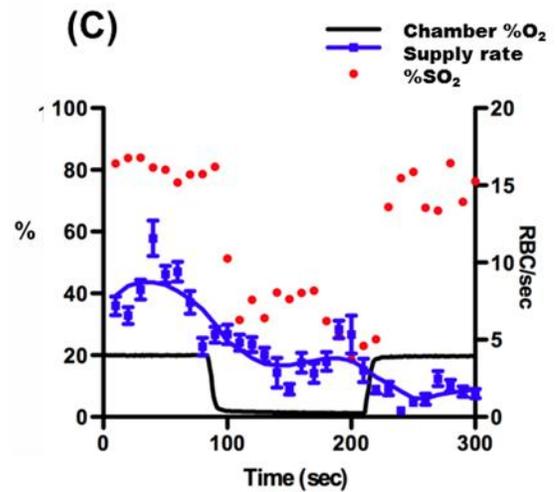

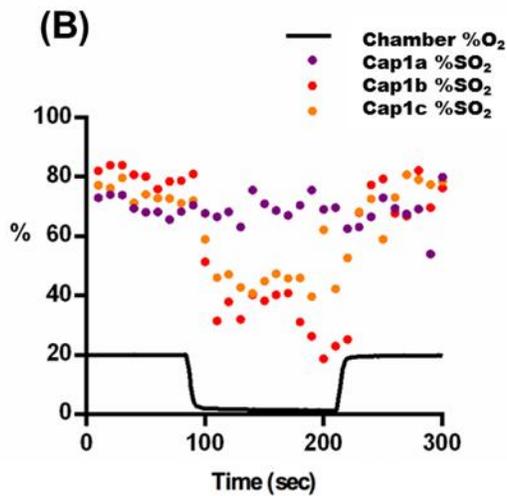

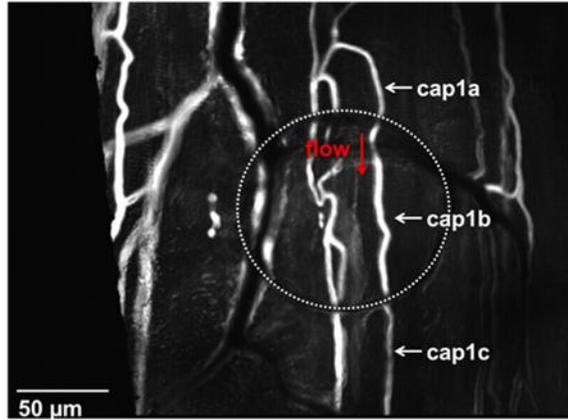

The aim of this set of experiments was to investigate the relationship between the onset of conducted microvascular response to low  $PO_2$  and the number of capillaries stimulated.  $O_2$  was exchanged through an  $O_2$  micro-outlet patterned in ultrathin glass/plastic sheet to live tissue in direct interface. Selected capillaries were positioned over the  $O_2$  micro-outlet with the aid of an inverted light microscope.  $O_2$  levels were oscillated at tissue surface and the erythrocyte  $SO_2$  and supply rate changes were measured and recorded. Unless otherwise stated, each capillary network analyzed in this manuscript has been captured from an independent EDL muscle preparation (total of 5 animals).

#### **4.3.1.1 *$O_2$ exchange through a circular micro-outlet (100 $\mu\text{m}$ in diameter)***

A selected capillary, designated as Cap1, on the surface of the EDL muscle was positioned on top of a circular micro-outlet 100  $\mu\text{m}$  in diameter (Figure 4.4A). The size of the circular micro-outlet allows for 1-2 capillaries to be affected by the local  $PO_2$  perturbations (Ghonaim et al. 2011, 2012). The  $O_2$  level in the chamber was decreased from 20% (152 mmHg) to 2% (15 mmHg) for a 120-second low  $O_2$  challenge and back to 20%. A video sequence was recorded over a six minute period beginning two minutes

before the low O<sub>2</sub> challenge. The video was postprocessed for changes in capillary hemodynamic parameters and erythrocyte SO<sub>2</sub>. Cap1 was divided into three sections designated as Cap1a, Cap 1b and Cap 1c, according to their position relative to the micro-outlet (Figure 4.4A). Each section was analyzed separately. The SO<sub>2</sub> profile for erythrocytes flowing in Cap1a, that is prior to entering the micro-outlet, seems to be unaffected by the low O<sub>2</sub> with an SO<sub>2</sub> level of  $\sim 68.6 \pm 10.1\%$  (SD, N=287) (Figure 4.4B). However, the SO<sub>2</sub> profile for erythrocytes flowing directly over the micro-outlet in Cap1b was strongly associated with the chamber O<sub>2</sub> level with a lag time of  $\sim 7$  sec (Figure 4.4B). The time delay in SO<sub>2</sub> changes relative to the chamber O<sub>2</sub> level was similar to previously reported values (Ghonaim et al. 2011). At 20% chamber O<sub>2</sub>, the SO<sub>2</sub> level in Cap1b was  $\sim 80.4 \pm 4.7\%$  (N=91). The SO<sub>2</sub> level then decreased to  $\sim 34.9 \pm 13.5\%$  (N=114) in response to lowering chamber O<sub>2</sub> (2%) followed by an increase to  $\sim 73.1 \pm 11.2\%$  (N=59) during recovery back to 20% O<sub>2</sub>. For Cap1c, the SO<sub>2</sub> profile also resembled the chamber O<sub>2</sub> level, yet it showed the erythrocytes were sensing higher tissue PO<sub>2</sub> relative to Cap 1b (Figure 4.4B). At 20% chamber O<sub>2</sub>, the SO<sub>2</sub> level in Cap1b was  $\sim 74.08 \pm 5.1\%$  (N=91). The SO<sub>2</sub> level then decreased to  $\sim 46.9 \pm 11.9\%$  (N=113) in response to lowering chamber O<sub>2</sub> (2%) followed by an increase to  $\sim 72.63 \pm 14.3\%$  (N=49) during recovery back to 20% O<sub>2</sub>. Although Cap1 clearly experienced changes in erythrocyte SO<sub>2</sub> in response to the local O<sub>2</sub> perturbation, no corresponding changes in capillary erythrocyte supply rate were measured (Figure 4.4C).

(A)

**Figure 4.4** EDL muscle preparation with transparent 100  $\mu\text{m}$  diameter micro-outlet positioned under the muscle. (A) A Variance image showing the microvascular network (20X) with flowing erythrocytes (white lines) and the location of the micro-outlet outlined by the white dashed line. A long capillary, in focus over its entire length, was

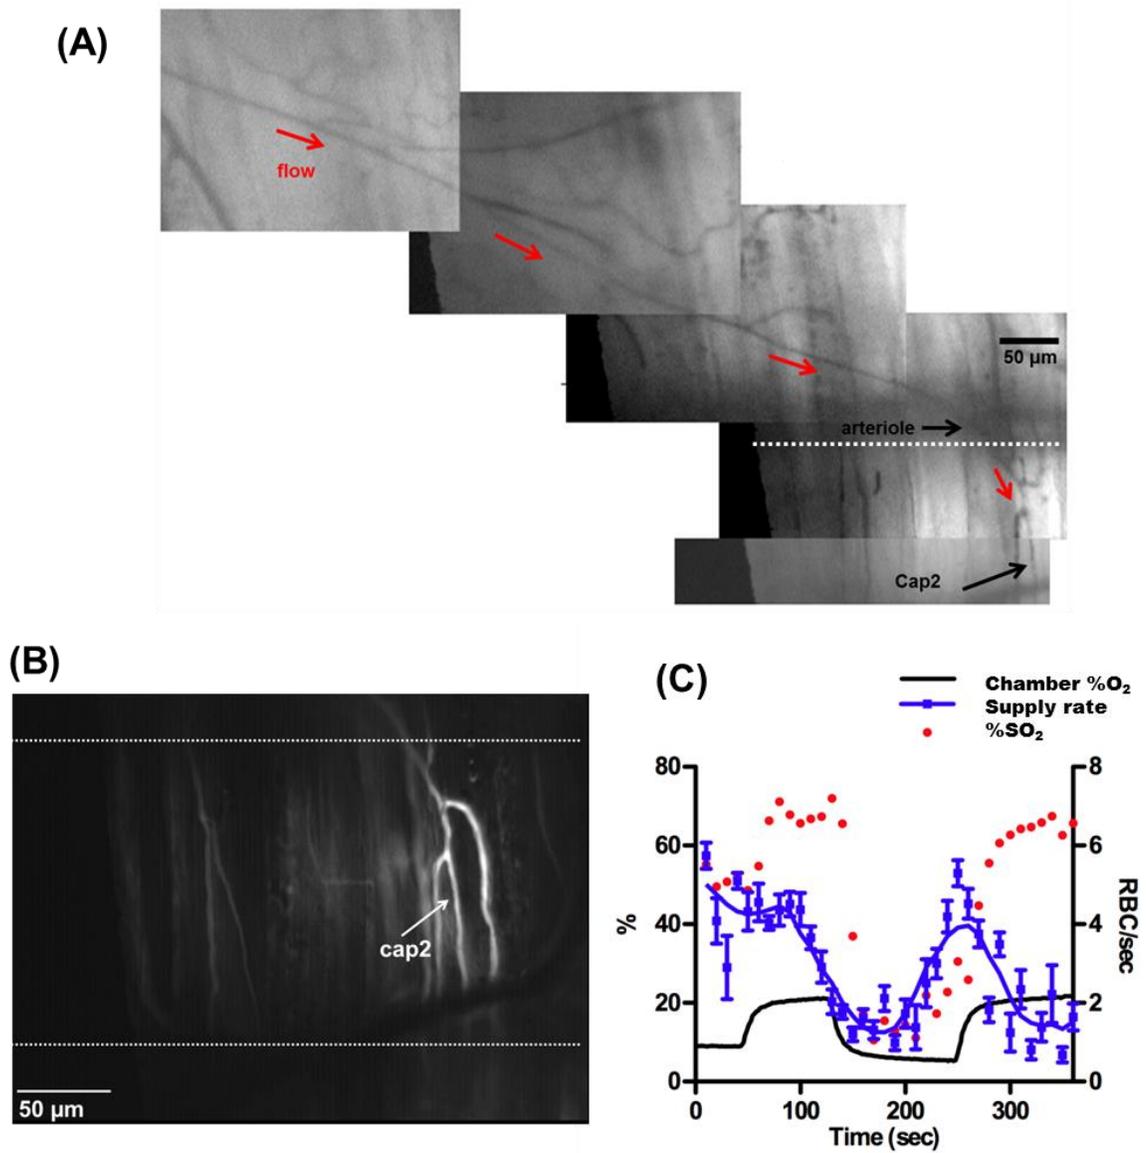

selected and positioned directly over the micro-outlet. This capillary, designated as Cap1, was sampled in three separate segments: Cap1a upstream of the micro-outlet, Cap1b directly over the outlet and Cap1c downstream of the outlet. O<sub>2</sub> levels in the chamber were oscillated in a square wave: 5% O<sub>2</sub> (PO<sub>2</sub> = 38 mmHg) for 30 seconds, 20% O<sub>2</sub> (PO<sub>2</sub> = ~150 mmHg) for 120 seconds, 2% O<sub>2</sub> (PO<sub>2</sub> = ~15 mmHg) for 120 seconds and back to 20% O<sub>2</sub>. A six minute video sequence was captured beginning as chamber O<sub>2</sub> was increased from 5% to 20%. (B) All three segments were analysed for changes in erythrocyte %SO<sub>2</sub> and supply rate. The erythrocyte %SO<sub>2</sub> level in Cap 1a experienced minimal changes in response to the PO<sub>2</sub> perturbations while the SO<sub>2</sub> profiles of Cap 1b and Cap 1c were more closely associated with chamber O<sub>2</sub> (C) however, the supply rate changes measured in Cap1b segment showed no correspondence with measured SO<sub>2</sub> changes. Measured supply rate data (10 sec mean) were plotted along with a fitted smoothing curve (blue solid line; Prism v 5.0, 2<sup>nd</sup> order smoothing polynomial function, number of neighbors to average = 6 neighbors on each size).

#### **4.3.1.2 O<sub>2</sub> exchange through the rectangular micro-slit (200 μm long x 1000 μm wide)**

In order to examine the effect of influencing a larger number of capillaries, a rectangular micro-slit (200 μm long x 1000 μm wide) was used and a small capillary branching network near the surface of the EDL muscle was positioned directly over the micro-slit (3-4 capillaries within the network) (Figure 4.5A,B). The tissue was equilibrated at 5% (38 mmHg PO<sub>2</sub>) O<sub>2</sub> level for 30 seconds. The O<sub>2</sub> level in the chamber was increased to 20% (152 mmHg) then decreased to 2% (15 mmHg) for a 120-second low O<sub>2</sub> challenge

and back to 20%. A video sequence was recorded over a six minute period beginning as chamber O<sub>2</sub> was increased from 5% to 20%. One capillary in the network (Cap2) was kept in sharp focus during the sample interval and the video was postprocessed for changes in hemodynamic parameters and erythrocyte SO<sub>2</sub> in a segment of this capillary. Similar to the previous observations, the PO<sub>2</sub> perturbations resulted in corresponding changes in the SO<sub>2</sub> profile in Cap2 with a delay time of ~7 sec (Figure 4.5C). At baseline chamber O<sub>2</sub> (5%), the SO<sub>2</sub> level in Cap2 was ~51.0±5.7% (N=55). Increasing chamber O<sub>2</sub> to 20% (at 50 sec) resulted in a corresponding increase in SO<sub>2</sub> to ~ 67.6±4.7% (N=79). The SO<sub>2</sub> level then decreased to ~21.1±12.0% (N=110) in response to lowering chamber O<sub>2</sub> (2%) (at 130) followed by an increase to ~61.3±9.6% (N=74) during recovery back to 20% O<sub>2</sub> (at 250sec). Stimulating the branching capillary network by altering capillary SO<sub>2</sub> resulted in associated changes in capillary erythrocyte supply rate as measured in Cap2 (Figure 4.5C). Increasing the chamber O<sub>2</sub> level from baseline of 5% up to 20% resulted in ~70% decrease in mean erythrocyte supply rate relative to baseline (minimum at ~1.3 RBC/sec at 190 sec) (Figure 4.5C). After reaching minimum value at ~190 sec, the supply level was observed to increase reaching a maximum of ~4.5 RBC/sec at ~ 250 sec (Figure 4.5). The increase in supply is associated with the decrease in SO<sub>2</sub> (at ~137 sec) in response to low chamber O<sub>2</sub> (at 130 sec). This indicates there is ~50 sec delay in supply rate response to low SO<sub>2</sub> measured from the time point at which SO<sub>2</sub> level decreases in response to low chamber O<sub>2</sub> to the time point at which supply rates increase above minimum value. Increasing chamber O<sub>2</sub> back to 20% (at 250 sec) resulted in sharp and near instantaneous decrease in supply rate to a minimum of ~1.3 RBC/sec.

Since the branching capillary network was positioned with the feeding arteriolar tree and terminal arteriolar end being upstream of the O<sub>2</sub> micro-slit (Figure 4.5A,B), the measured microvascular responses were probably conducted upstream from the capillary bed into the supplying arteriolar network.

**Figure 4.5** (A, B) A selected capillary, Cap2, in a branching capillary network, was positioned directly over a rectangular micro-slit (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long) outlined by white dashed line with the arteriolar tree upstream of the micro-slit. Cap2 was analysed for changes in erythrocyte %SO<sub>2</sub> and supply rate (RBC/sec) as O<sub>2</sub> levels in the

chamber are oscillated in a square wave. The tissue was equilibrated at 5% O<sub>2</sub> (38 mmHg PO<sub>2</sub>) level for 30 seconds. The O<sub>2</sub> level in the chamber was increased to 20% (~152 mmHg) then decreased to 2% (~15.2 mmHg) for a 120 second low O<sub>2</sub> challenge and back to 20%. A six minute video sequence was captured beginning 2 min prior to the low O<sub>2</sub> challenge. (C) The erythrocyte SO<sub>2</sub> profile for Cap 2 resembles that of chamber O<sub>2</sub>. Stimulating the branching capillary network results in measured changes in erythrocyte supply rate. Measured supply rate data (10 sec mean) were plotted along with a fitted smoothing curve (blue solid line; Prism v 5.0, 2<sup>nd</sup> order smoothing polynomial function, number of neighbors to average = 6 neighbors on each size).

### **4.3.2 Examining the reproducibility of the microvascular response to the SO<sub>2</sub> changes in selected capillaries**

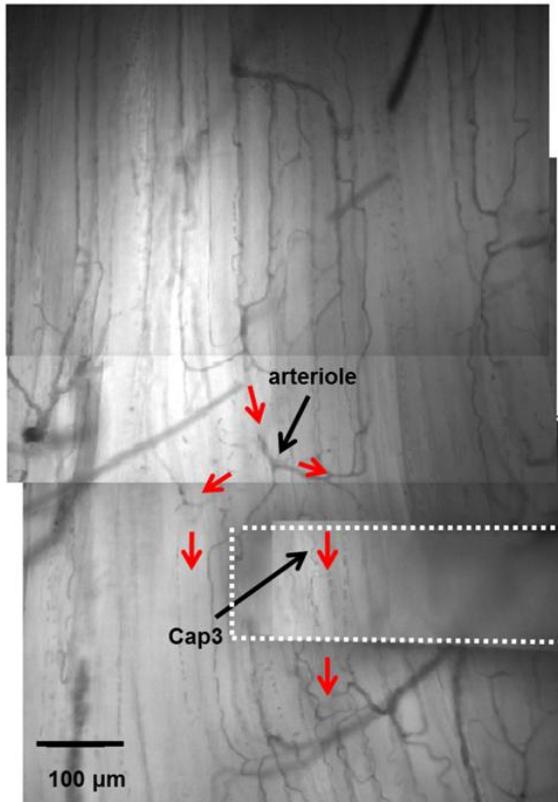

#### **4.3.2.1 *Measuring reproducibility over consecutive capture sequences***

In order to test the reproducibility of the supply rate responses to capillary SO<sub>2</sub> changes, the low O<sub>2</sub> perturbation was repeated over two video sequences, with a 20 min time gap on a selected capillary branching network (5-6 capillaries within the network) positioned directly over the rectangular micro-slit (Figure 4.6A,B). The tissue was equilibrated at 5% O<sub>2</sub> (38 mmHg PO<sub>2</sub> level) for 60 seconds. The O<sub>2</sub> level in the chamber was increased to 20% (152 mmHg) then decreased to 2% (15 mmHg) for a 160-second low O<sub>2</sub> challenge and back to 20%. A video sequence was recorded over an eight minute period

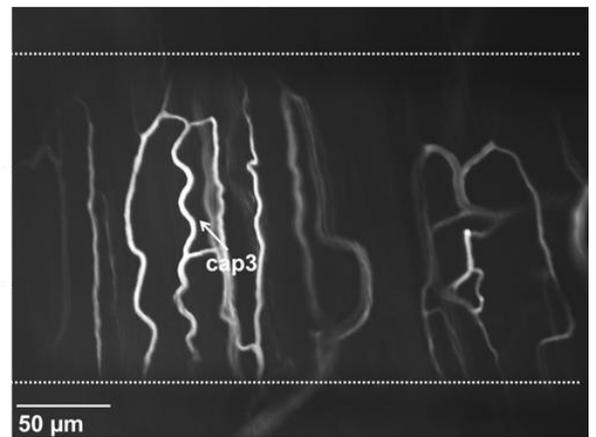

beginning one minute before the increase in chamber O<sub>2</sub> from 5 to 20%. The tissue was then allowed to equilibrate with chamber O<sub>2</sub> of 5% for 20 min after which the same O<sub>2</sub> perturbation was repeated. A selected capillary in the network designated Cap3 was analyzed for changes in erythrocyte SO<sub>2</sub> and hemodynamic parameters. In both consecutive sequences, the erythrocyte SO<sub>2</sub> profile for Cap3 was closely associated with the chamber O<sub>2</sub> a delay time of ~7 sec as previously measured (Figure 4.6C,D). In the first captured sequence (Figure 4.6C), the SO<sub>2</sub> level in Cap3 at baseline chamber O<sub>2</sub> (5%) was ~67.4±2.2% (N=8). Increasing chamber O<sub>2</sub> to 20% (at 70 sec) resulted in a corresponding increase in SO<sub>2</sub> to ~87.0±2.0% (N=11). The SO<sub>2</sub> level then decreased to ~61.7±4.6% (N=15) in response to lowering chamber O<sub>2</sub> (2% at 190 sec) followed by an increase to ~85.8±3.0% (N=15) during recovery back to 20% O<sub>2</sub> (at 340 sec). In general, the measured SO<sub>2</sub> changes in the second captured sequence (20 min later) due to the PO<sub>2</sub> perturbation (Figure 4.6D) were comparable to those measured in the first sequence (Figure 4.6C). At baseline chamber O<sub>2</sub> (5%), the SO<sub>2</sub> level in Cap3 was ~70.4±3.3% (N=12). Increasing chamber O<sub>2</sub> to 20% (at 120 sec) resulted in a corresponding increase in SO<sub>2</sub> to ~87.6±6.3% (N=14). The SO<sub>2</sub> level then decreased to ~57.2±4.5% (N=13) in response to lowering chamber O<sub>2</sub> (2% at 250 sec) followed by an increase to ~87.1±1.2% (N=10) during recovery back to 20% O<sub>2</sub> (at 400 sec). During the first PO<sub>2</sub> perturbation (Figure 4.6C), increasing chamber O<sub>2</sub> level from baseline to 20% resulted in 50% decrease in supply rate relative to baseline (minimum of ~10 RBC/sec at 210 sec). After reaching minimum value, supply levels increased in response to low SO<sub>2</sub> (at 200 sec) reaching a maximum of ~16 RBC/sec at 340 sec, which was slightly below that at

baseline ( $\sim 18.3 \pm 1.7$  RBC/sec, N=8). The delay time in supply rate response to decrease in  $\text{SO}_2$  level was  $\sim 10$  sec. The increase in the supply rate was associated with a re-oxygenation effect as observed in the  $\text{SO}_2$  profile at  $\sim 250$  seconds (Figure 4.6C). Increasing chamber  $\text{O}_2$  back to 20% (at 340 sec) resulted in sharp and near instantaneous decrease in supply rate to a minimum of  $\sim 7$  RBC/sec. Repeating the same  $\text{PO}_2$  perturbation on the selected field of view 20 minutes later resulted in similar supply rate responses (Figure 4.6D). In the second sequence, the baseline supply rate level for Cap3 was slightly lower ( $\sim 14.6 \pm 1.2$  RBC/sec, N=13) and the overall supply rate profile was slightly shifted to lower values. Increasing chamber  $\text{O}_2$  level from baseline to 20% resulted in 80% decrease in supply rate relative to baseline (minimum at  $\sim 2.9$  RBC/sec at 270 sec). After reaching minimum value, supply levels increased in response to low  $\text{SO}_2$  (at 260 sec) bringing the supply rate level up to slightly below that at baseline with a maximum of  $\sim 12$  RBC/sec. The measured delay time in supply rate response to decrease in  $\text{SO}_2$  level was similar to that measured during the first perturbation  $\sim 10$  sec. Increasing chamber  $\text{O}_2$  back to 20% (at 400 sec) resulted in sharp and instantaneous decrease in supply rate to a minimum of  $\sim 7.3$  RBC/sec. A similar flow response was observed in the other capillaries in the field of view. Since the feeding arteriolar end was positioned upstream of the  $\text{O}_2$  micro-slit (Figure 4.6A,B), the measured microvascular responses are anticipated to be conducted from the capillary bed to the supplying arterioles.

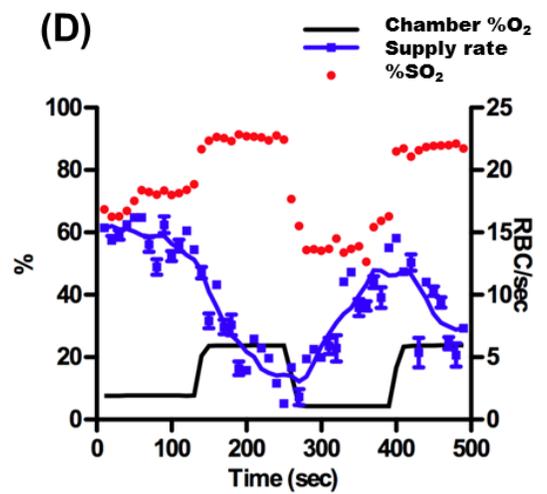

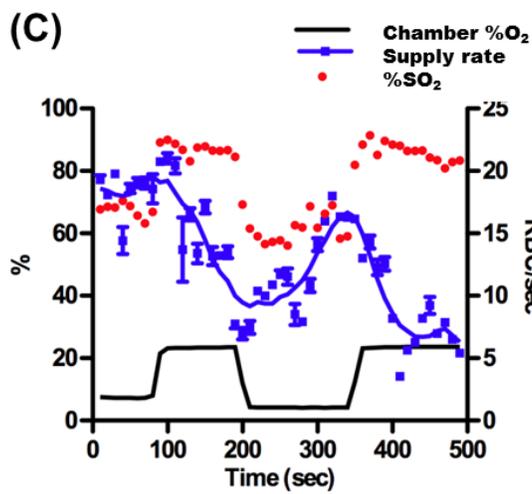

(A)

(B)

20 min later

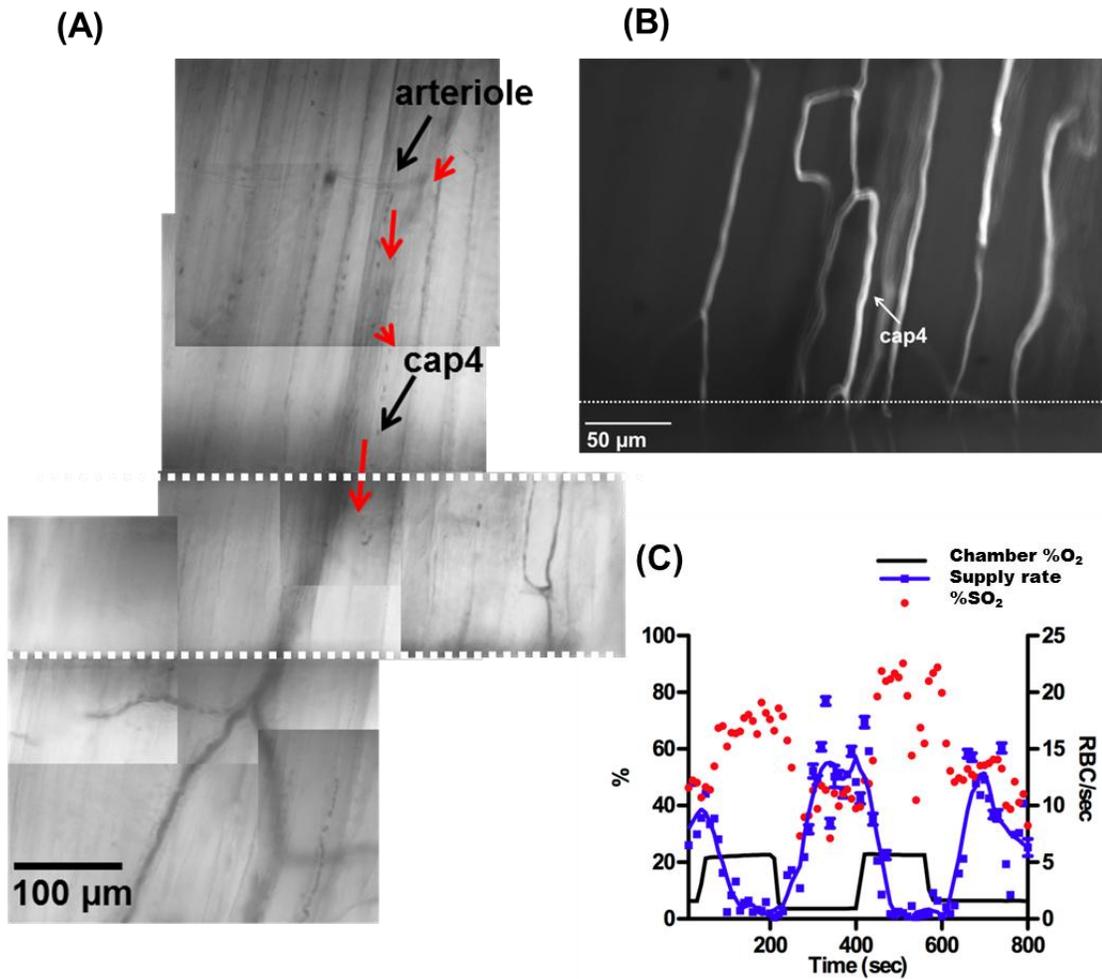

**Figure 4.6** (A, B) A selected capillary, Cap3, in a branching capillary network, is positioned directly over a rectangular micro-slit (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long) outlined by white dashed line with the arteriolar tree upstream of the micro-slit. Cap3 was analysed for changes in erythrocyte %SO<sub>2</sub> and supply rate as O<sub>2</sub> levels in the chamber are oscillated in a square wave. The tissue is equilibrated at 5% O<sub>2</sub> (38 mmHg PO<sub>2</sub>) level for 60 seconds. The O<sub>2</sub> level in the chamber is increased to 20% (~152 mmHg) then decreased to 2% (~15.2 mmHg) for a 160 second low O<sub>2</sub> challenge and back to 20%. An eight minute video sequence is captured beginning 3 min prior to the low O<sub>2</sub> challenge. (C) The SO<sub>2</sub> profile for Cap3 is closely associated with chamber O<sub>2</sub> and SO<sub>2</sub> changes result in corresponding changes in supply rate. (D) Similar SO<sub>2</sub> and supply rate responses are measured after repeating the PO<sub>2</sub> oscillation approximately 20 min following the perturbation shown in (C). Measured supply rate data were plotted along with a smoothing curve (blue solid line; Prism v 5.0, 2<sup>nd</sup> order smoothing polynomial function, number of neighbors to average = 6 neighbors on each size).

#### **4.3.2.2 Measuring reproducibility over consecutive PO<sub>2</sub> perturbations in a single sequence**

The reproducibility of the supply rate responses to capillary SO<sub>2</sub> changes were also tested by repeating the PO<sub>2</sub> perturbation in the same sequence. Erythrocyte SO<sub>2</sub> and supply rate changes were measured in a selected capillary (Cap4) positioned upstream of the micro-slit with capillary venular end positioned over the micro-slit (Figure 4.7A,B). Cap4 is one of ~6-8 capillaries draining directly over the micro-slit originating from same upstream

arteriole. The tissue was initially equilibrated at 5% (38 mmHg PO<sub>2</sub>) O<sub>2</sub> level for 30 seconds. O<sub>2</sub> levels in the chamber were the oscillated in two consecutive square waves (period ~ 400 seconds). The O<sub>2</sub> level in the chamber was increased to 20% (152 mmHg) then decreased to 2% (15 mmHg) for a 190 second low O<sub>2</sub> challenge and back to 20%. The chamber O<sub>2</sub> levels were then decreased back to baseline level (5%). A video sequence was recorded over a thirteen minute period (16,146 frames x 2) beginning as the chamber O<sub>2</sub> was increased from 5 to 20%. The measured erythrocyte SO<sub>2</sub> profile for Cap4 was closely associated with the chamber O<sub>2</sub> a delay time of ~ 20-30 sec, which is 2-3 times higher than previously measured (Figure 4.7C). The measured baseline SO<sub>2</sub> level was ~46.4±2.1% (N=6). In the first increase in chamber O<sub>2</sub> to 20% (at 50 sec), the SO<sub>2</sub> level in Cap4 increased to ~ 67.1±6.1% (N=19). The SO<sub>2</sub> level then decreased to ~41.1±6.0% (N=17) in response to lowering chamber O<sub>2</sub> (2% at 220 sec). The following increase in chamber O<sub>2</sub> back to 20% (at 410 sec) resulted in a corresponding increase in SO<sub>2</sub> to ~75.7±14.1% (N=18) followed by a decrease to ~48.8±6.5 (N=19) at baseline O<sub>2</sub> (5% at 570 sec). The results showed strong and reproducible supply rate response to altered erythrocyte SO<sub>2</sub>. For both perturbation cycles, the supply rate was shut down completely in response to 20% chamber O<sub>2</sub> (Figure 4.7C). On the other hand, decreasing chamber O<sub>2</sub> resulted in supply rate increase from zero flow to ~30% above baseline (9.0±2.0 RBC/sec, N=6) in both cycles (Figure 4.7C). Zero time delay in supply rate response to low SO<sub>2</sub> was measured at both perturbation cycles. Also, although the selected section in Cap4 was within 50 μm upstream of the micro-slit, the feeding arteriolar end was more than 200 μm upstream. This suggested the responses observed in

Cap4 are probably conducted several hundred  $\mu\text{m}$  upstream into the arteriolar tree to alter supply rate.

**Figure 4.7** (A, B) A selected capillary, Cap4, in a branching capillary network, is positioned upstream of a rectangular micro-slit (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long) outlined by white dashed with the venular end of the capillary positioned directly over the micro-

slit. The feeding arteriolar end upstream of the selected capillary and flow direction are indicated (A). Cap4 was analysed for changes in erythrocyte %SO<sub>2</sub> and supply rate as O<sub>2</sub> levels in the chamber are oscillated in two consecutive square waves (period ~ 400 seconds). The tissue is equilibrated at 5% (38 mmHg PO<sub>2</sub>) O<sub>2</sub> level for 30 seconds. The O<sub>2</sub> level in the chamber is increased to 20% (~152 mmHg) then decreased to 2% (~15.2 mmHg) for a 190 second low O<sub>2</sub> challenge and back to 20%. The chamber O<sub>2</sub> levels were then decreased back to baseline level (5%). A thirteen minute video sequence is captured beginning 2 min prior to decreasing chamber O<sub>2</sub>. (C) The SO<sub>2</sub> profile for Cap4 is closely associated with chamber O<sub>2</sub> profile. Altering erythrocyte SO<sub>2</sub> in the selected capillary result in strong reproducible supply rate responses. Measured supply rate data were plotted along with a smoothing curve (blue solid line; Prism v 5.0, 2<sup>nd</sup> order smoothing polynomial function, number of neighbors to average = 6 neighbors on each size).

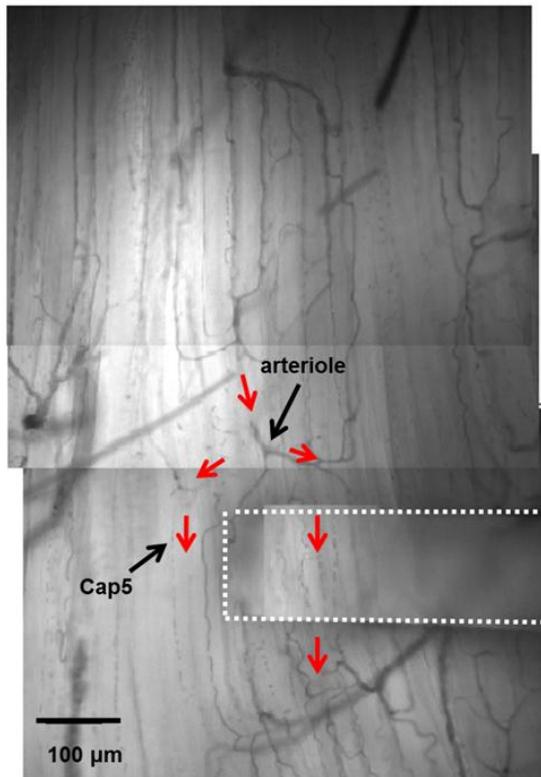

### **4.3.3 Examining the influence of the PO<sub>2</sub> perturbations on capillaries positioned near the micro-slit**

In order to examine the effect of the O<sub>2</sub> exchange micro-slit on surrounding capillaries *in vivo*, erythrocyte SO<sub>2</sub> and supply rate changes were measured in a selected capillary (Cap 5) positioned within 50 μm from the side edge of micro-slit (Figure 4.8A,B). The arteriole feeding Cap5 branches off the same arterial tree feeding Cap3 network (see above). The tissue was initially equilibrated at 5% (38 mmHg PO<sub>2</sub>) level for 60 seconds. The O<sub>2</sub> level in the chamber was increased to 20% (152 mmHg) then decreased to 2% (15 mmHg) for a 130 second low O<sub>2</sub> challenge and back to 20%. A video sequence was

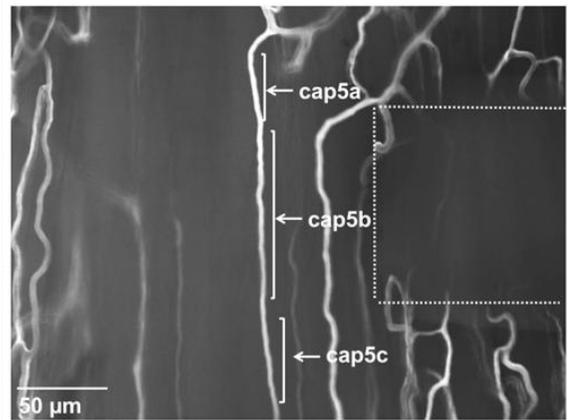

recorded over an eight minute period beginning 3 minutes prior to the low O<sub>2</sub> challenge. Cap5 was divided into three sections Cap5a, Cap5b, and Cap5c (Figure 4.8B) and each section was individually analyzed. The results indicated that Cap5a, which is located furthest upstream from the micro-slit and directly downstream from the feeding arteriole, experienced least changes in erythrocyte SO<sub>2</sub> relative to Cap5b and Cap 5c (Figure 4.9B). At baseline chamber O<sub>2</sub> (5%), the mean SO<sub>2</sub> level in Cap5a was  $\sim 63.4 \pm 2.6\%$  (N=6). Increasing chamber O<sub>2</sub> to 20% (at 70 sec) resulted in a corresponding increase in mean SO<sub>2</sub> to  $\sim 83.2 \pm 5.6\%$  (N=11). The mean SO<sub>2</sub> level then decreased to  $\sim 74.8 \pm 3.8\%$  (N=12) in response to lowering chamber O<sub>2</sub> (2% at 170 sec) followed by an increase to  $\sim 84.8 \pm 4.7\%$  (N=8) during recovery back to 20% O<sub>2</sub> at 300 sec. Downstream from Cap5a, the sensed SO<sub>2</sub> changes were larger and the measured three dimensional SO<sub>2</sub> profiles along the capillary length were more closely associated with chamber O<sub>2</sub> (Figure 4.9A). In Cap5b, baseline mean SO<sub>2</sub> level was  $\sim 47.6 \pm 2.7\%$  (N=6). Increasing chamber O<sub>2</sub> to 20% resulted in a corresponding increase in mean SO<sub>2</sub> to  $\sim 73.6 \pm 5.6\%$  (N=11). The mean SO<sub>2</sub> level then decreased to  $\sim 49.2 \pm 3.7\%$  (N=12) in response to lowering chamber O<sub>2</sub> (2%) followed by an increase to  $\sim 75.4 \pm 4.3\%$  (N=8) during recovery back to 20% O<sub>2</sub>. The greatest SO<sub>2</sub> changes in measured in Cap5c. At baseline, the mean SO<sub>2</sub> level in Cap5c was  $\sim 36.8 \pm 1.3\%$  (N=6). The increase in chamber O<sub>2</sub> resulted in a corresponding increase in mean SO<sub>2</sub> to  $\sim 68.4 \pm 7.4\%$  (N=11). Decreasing chamber O<sub>2</sub> (2%) resulted in decreasing mean SO<sub>2</sub> level to  $\sim 38.5 \pm 5.1\%$  (N=12) followed by an increase to  $\sim 70.5 \pm 4.3\%$  (N=8) during recovery back to 20% O<sub>2</sub>. Despite the relatively smaller changes in SO<sub>2</sub> in Cap5a, supply rate responses were measured in with  $\sim 40$  sec delay time in response to low SO<sub>2</sub> at

180 sec (Figure 4.9B). The measured supply rate profile was almost identical in all three sections of Cap5. However, the association between supply rate responses and  $\text{SO}_2$  changes was stronger in Cap5b and Cap5c relative to Cap5a (Figure 4.9B). The baseline supply rates in Cap5a, 5b, and 5c were  $\sim 6.1 \pm 1.0$  RBC/sec N=6,  $\sim 5.9 \pm 1.0$  RBC/sec N=6, and  $\sim 5.5 \pm 1.0$  RBC/sec N=6, respectively. Increasing chamber  $\text{O}_2$  to 20% resulted in  $\sim 60\%$  decrease in supply rate relative to baseline (minimum of  $\sim 3$  RBC/sec at 220 sec). The supply rate increased  $\sim 40$  sec following decrease in  $\text{SO}_2$  (at  $\sim 180$  seconds) to a maximum of  $\sim 5.5$  RBC/sec at 280 sec to match baseline level (Figure 4.9B). Increasing chamber  $\text{O}_2$  back to 20% resulted in sharp and instantaneous decrease in supply rate to a minimum of  $\sim 1.5$  RBC/sec. The increase in supply rate in response to low  $\text{SO}_2$  resulted in slight re-oxygenation observed at  $\sim 230$  seconds which seemed to compensate for the decrease in erythrocyte  $\text{SO}_2$ . This effect was most pronounced in Cap5a and decreased downstream. The results indicated that the effect of the micro-slit might be extending slightly beyond  $50 \mu\text{m}$ , which was the radial diffusion distance proposed in our previously described theoretical model (Ghonaim et al. 2013)

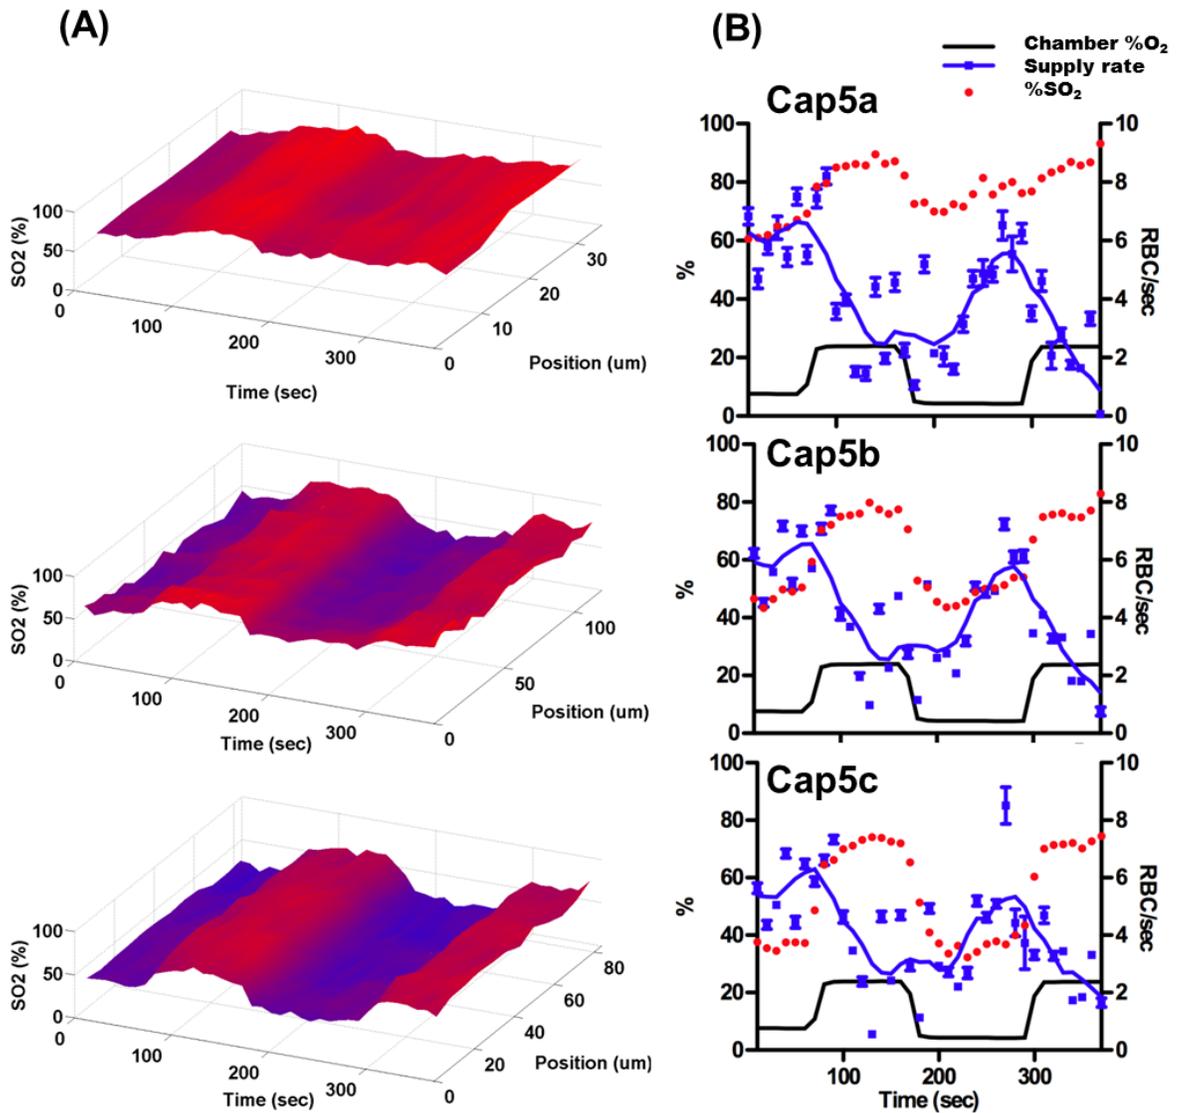

(A)

(B)

**Figure 4.8** (A, B) A selected capillary, Cap5, is positioned outside adjacent to the edge of the rectangular micro-slit (1000 μm wide x 200 μm long) outlined by white dashed line. (A) The feeding arteriolar end upstream of the selected capillary and flow direction are indicated. (B) Cap5 was divided into three sections, Cap 5a, Cap 5b, and Cap 5c and each section was analysed individually for changes in erythrocyte  $SO_2$  and supply rate.

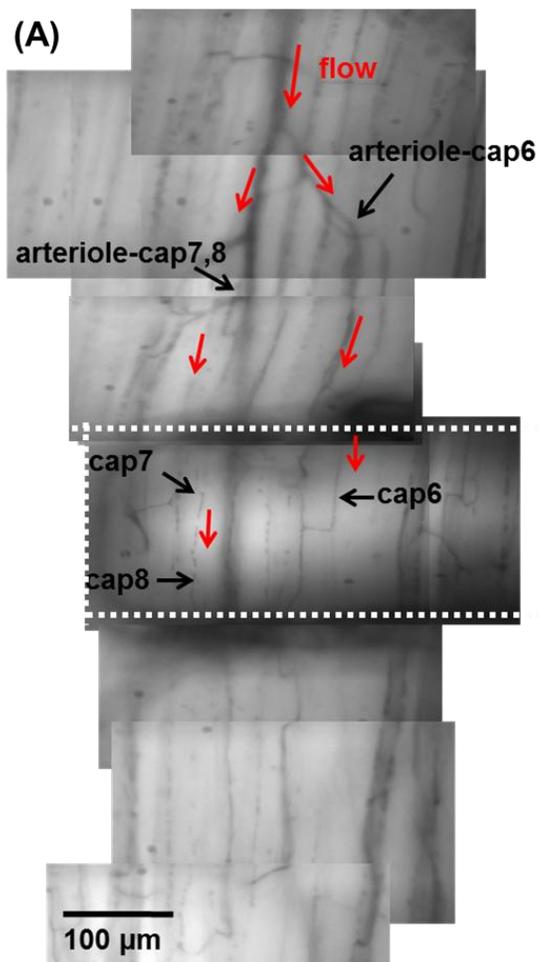

**Figure 4.9** Cap5 (see Figure 4.8) was analysed for changes in erythrocyte %SO<sub>2</sub> and supply rate as O<sub>2</sub> levels in the chamber are oscillated in a square wave. The tissue is equilibrated at 5% (38 mmHg PO<sub>2</sub>) O<sub>2</sub> level for 60 seconds. The O<sub>2</sub> level in the chamber is increased to 20% (~152 mmHg) then decreased to 2% (~15.2 mmHg) for a 130 second low O<sub>2</sub> challenge and back to 20%. An eight minute video sequence was captured

beginning 3 min prior to the low O<sub>2</sub> challenge. (A) The three dimensional (3D) SO<sub>2</sub> plots displaying SO<sub>2</sub> values across capillary section length with time (B) The SO<sub>2</sub> profiles for Cap5 sections further downstream (closer to micro-slit) are more closely associated with chamber O<sub>2</sub>. The SO<sub>2</sub> changes in Cap5 result in corresponding changes in supply rate. Measured supply rate data were plotted along with a smoothing curve (blue solid line; Prism v 5.0, 2<sup>nd</sup> order smoothing polynomial function, number of neighbors to average = 6 neighbors on each size).

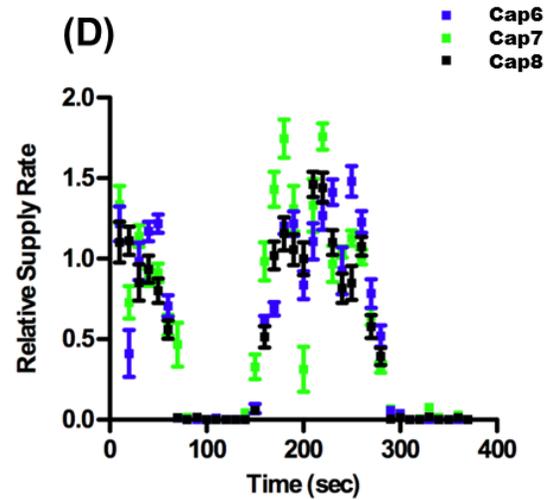

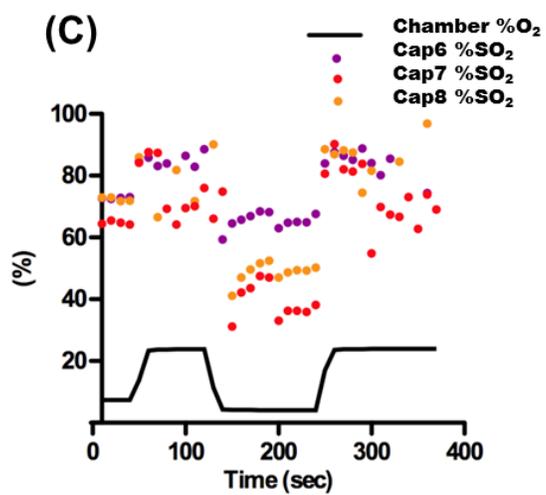

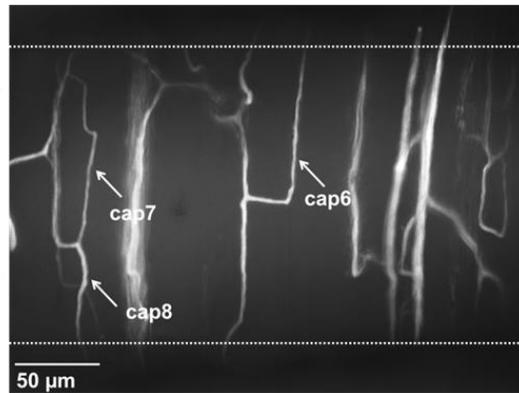

#### **4.3.4 Measuring relative changes in supply rate in response to local PO<sub>2</sub> perturbations**

In this experiment, relative changes in supply rate in response to altering SO<sub>2</sub> level in selected capillaries *in vivo* were estimated. Supply rate changes were measured and normalized against baseline mean supply rate in three selected capillaries. The capillaries originate from two branching capillary network fed by the same upstream arterial tree in the same field of view (total of 8-9 capillaries). The three capillaries designated Cap6, Cap7, and Cap8 (Figure 4.10A,B) were positioned directly over the rectangular micro-slit (Figure 4.10A,B). The tissue was initially equilibrated at 5% (38 mmHg PO<sub>2</sub>) O<sub>2</sub> level for 30 seconds. The O<sub>2</sub> level in the chamber was increased to 20% (at 50 sec) (152 mmHg) then decreased to 2% (at 130 sec) (15 mmHg) for low O<sub>2</sub> challenge and back to 20% (at 250 sec). A video sequence was recorded over an eight minute period beginning 2 minutes prior to the low O<sub>2</sub> challenge. The measured SO<sub>2</sub> profiles for all three capillaries were closely associated with the chamber O<sub>2</sub> level (Figure 4.10C). In Cap6, baseline

mean SO<sub>2</sub> level was  $\sim 72.7 \pm 0.2\%$  (N=4). Increasing chamber O<sub>2</sub> to 20% resulted in a corresponding increase in mean SO<sub>2</sub> to  $\sim 85.0 \pm 2.0\%$  (N=7). The mean SO<sub>2</sub> level then decreased to  $\sim 65.3 \pm 2.6\%$  (N=11) in response to lowering chamber O<sub>2</sub> (2%) followed by an increase to  $\sim 84.0 \pm 4.4\%$  (N=9) during recovery back to 20% O<sub>2</sub>. In Cap7, baseline mean SO<sub>2</sub> level was  $\sim 64.7 \pm 0.6\%$  (N=4). Increasing chamber O<sub>2</sub> to 20% resulted in a corresponding increase in mean SO<sub>2</sub> to  $\sim 74.9 \pm 8.7\%$  (N=10). The mean SO<sub>2</sub> level then decreased to  $\sim 39.1 \pm 5.7\%$  (N=10) in response to lowering chamber O<sub>2</sub> (2%) followed by an increase to  $\sim 73.5 \pm 9.8\%$  (N=13) during recovery back to 20%. In Cap8, baseline mean SO<sub>2</sub> level was  $\sim 72.3 \pm 0.6\%$  (N=4). Increasing chamber O<sub>2</sub> to 20% resulted in a corresponding increase in mean SO<sub>2</sub> to  $\sim 80.7 \pm 9.4\%$  (N=6). The mean SO<sub>2</sub> level then decreased to  $\sim 48.7 \pm 3.2\%$  (N=10) in response to lowering chamber O<sub>2</sub> (2%) followed by an increase to  $\sim 86.1 \pm 6.4\%$  (N=8) during recovery back to 20%. Despite the variability in the mean SO<sub>2</sub> levels at baseline and during the perturbations in the three selected capillaries, the relative changes in supply rate in response to the SO<sub>2</sub> changes were consistent (Figure 4.10D). Supply rate increased by  $\sim 50\%$  above baseline in response to low O<sub>2</sub> and was almost shut down in response to the 20% chamber O<sub>2</sub> level (Figure 4.10D). Zero delay time was measured between the time point at which SO<sub>2</sub> level decreases in response to low chamber O<sub>2</sub> and the time point at which supply rate increases (Figure 4.10D).

(B)

**Figure 4.10** (A, B) Selected capillary, Cap6, Cap7, and Cap8, are positioned directly over the rectangular micro-slit (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long) outlined by white dashed line. (A) The feeding arteriolar end upstream of the selected capillary and flow direction are indicated. Cap6 is supplied by one terminal branch of the arteriolar tree; Cap7 & Cap8 are supplied by another branch. Both terminal arterioles branch from the same parent arteriole. (B) Cap6, 7, 8 as visualised at 20X were analysed for changes in erythrocyte  $\text{SO}_2$  and supply rate. Capillaries were analysed for changes in erythrocyte % $\text{SO}_2$  and supply rate as  $\text{O}_2$  levels in the chamber are oscillated in a square wave. The tissue is equilibrated at 5% (38 mmHg  $\text{PO}_2$ )  $\text{O}_2$  level for 30 seconds. The  $\text{O}_2$  level in the chamber is increased to 20% (~152 mmHg) then decreased to 2% (~15.2 mmHg) for a 120 second low  $\text{O}_2$  challenge and back to 20%. An eight minute video sequence is captured beginning 2 min prior to the low  $\text{O}_2$  challenge. (C) The erythrocyte  $\text{SO}_2$  profiles in Cap 6, 7, and 8 are closely associated with chamber  $\text{O}_2$ . (D) Supply rates in the three selected capillaries were normalized against mean baseline supply rate to display relative changes. Change in capillary  $\text{SO}_2$  result in very similar normalized supply rate responses in all three capillary segments.

#### **4.3.5 Measuring changes in erythrocyte velocity and capillary hematocrit in response to local $\text{PO}_2$ perturbations and their contribution to observed supply rate changes**

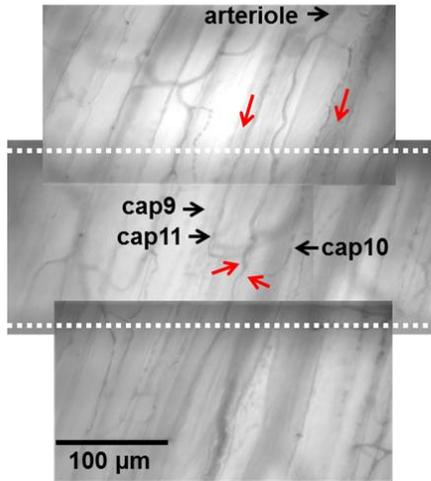

Next, we tested whether observed supply rate responses to altered erythrocyte  $\text{SO}_2$  are due to changes in erythrocyte velocity or changes in capillary hematocrit. Changes in

erythrocyte  $\text{SO}_2$ , supply rate, erythrocyte velocity ( $\mu\text{m}/\text{sec}$ ), and capillary hematocrit (%) in response to the local  $\text{PO}_2$  perturbation were measured in three selected capillaries in a branching network (total of  $\sim 5$  capillaries in a network). The three capillaries designated Cap9, Cap10, and Cap11 (Figure 4.11A, B) were positioned with their venular ends directly over the rectangular micro-slit and the feeding arteriole positioned upstream of the micro-slit (Figure 4.11B). The chamber  $\text{O}_2$  levels were oscillated in two consecutive square waves (period  $\sim 400$  seconds). The tissue was initially equilibrated at 5% (38 mmHg  $\text{PO}_2$ )  $\text{O}_2$  level for 30 seconds. For each  $\text{PO}_2$  oscillation, The  $\text{O}_2$  level in the chamber was increased to 20% (at 50 sec) (152 mmHg) then decreased to 2% (15 mmHg) for a 100 second low  $\text{O}_2$  challenge and back to 20%. A video sequence was recorded over an eight minute period beginning 2 minutes prior to the low  $\text{O}_2$  challenge. The measured  $\text{SO}_2$  profiles for all three capillaries were almost identical and were closely associated with the chamber  $\text{O}_2$  level (Figure 4.11C). In Cap9, baseline mean  $\text{SO}_2$  level was  $\sim 43.5 \pm 3.7\%$  (N=4). The first increase in chamber  $\text{O}_2$  to 20% resulted in a corresponding increase in mean  $\text{SO}_2$  to  $\sim 81.8 \pm 10.5\%$  (N=20). The mean  $\text{SO}_2$  level then decreased to  $\sim 67.6 \pm 5.6\%$  (N=20) in response to lowering chamber  $\text{O}_2$  (2%) followed by an increase to  $\sim 93.7 \pm 8.6\%$  (N=17) during recovery back to 20%  $\text{O}_2$ . The chamber  $\text{O}_2$  levels were then decreased back to baseline (5%) bringing mean  $\text{SO}_2$  level to  $\sim 63.0 \pm 8.1\%$  (N=19). In Cap10, baseline mean  $\text{SO}_2$  level was  $\sim 62.7 \pm 1.9\%$  (N=4). The first increase in chamber  $\text{O}_2$  to 20% resulted in a corresponding increase in mean  $\text{SO}_2$  to  $\sim 81.6 \pm 6.7\%$  (N=20). The mean  $\text{SO}_2$  level then decreased to  $\sim 54.5 \pm 4.3\%$  (N=20) in response to lowering chamber  $\text{O}_2$  (2%) followed by an increase to  $\sim 87.9 \pm 4.0\%$  (N=17) during recovery back to 20%  $\text{O}_2$ .

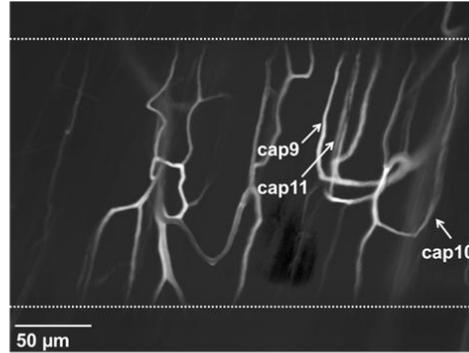

The chamber O<sub>2</sub> levels were then decreased back to baseline (5%) bringing mean SO<sub>2</sub> level to  $\sim 69.4 \pm 2.3\%$  (N=19). In Cap11, baseline mean SO<sub>2</sub> level was  $\sim 58.7 \pm 3.5\%$  (N=4). The first increase in chamber O<sub>2</sub> to 20% resulted in a corresponding increase in mean SO<sub>2</sub> to  $\sim 84.8 \pm 6.0\%$  (N=20). The mean SO<sub>2</sub> level then decreased to  $\sim 47.7 \pm 9.5\%$  (N=20) in response to lowering chamber O<sub>2</sub> (2%) followed by an increase to  $\sim 89.6 \pm 7.7\%$  (N=17) during recovery back to 20% O<sub>2</sub>. The chamber O<sub>2</sub> levels were then decreased back to baseline (5%) bringing mean SO<sub>2</sub> level to  $\sim 60.8 \pm 3.7\%$  (N=19). Supply rate changes in response to altered SO<sub>2</sub> levels were observed in all three capillaries (Figure 4.11D) and were closely associated with changes in capillary hematocrit (Figure 4.11F) rather than erythrocyte velocity (Figure 4.11E). In Cap9, the baseline supply rate, velocity, and hematocrit were measured at  $\sim 7.0 \pm 0.2$  RBC/sec, N=4,  $\sim 261.1 \pm 18.6$   $\mu\text{m}/\text{sec}$ , N=4, and  $\sim 9.5 \pm 1.2\%$ , N=4, respectively. Increasing chamber O<sub>2</sub> to 20% resulted in  $\sim 50\%$  decrease in supply rate and a 17% decrease in hematocrit relative to baseline. A delay time of  $\sim 50$  sec was measured for supply rate increase in response to decrease in SO<sub>2</sub> (at  $\sim 220$  seconds). The supply rate level increased to slightly above baseline with a maximum of  $\sim 9.8$  RBC/sec (at 420 sec) which was also associated with increase in hematocrit to a maximum of  $\sim 14.5\%$  (Figure 4.11D,F). Increasing chamber O<sub>2</sub> back to 20% resulted in sharp and instantaneous decrease in supply rate to a minimum of  $\sim 1.5$  RBC/sec (at 650 sec) and in hematocrit to a minimum of  $\sim 4\%$ . Decreasing chamber O<sub>2</sub> level back to baseline resulted in supply rate increase to a maximum of  $\sim 11$  RBC/sec and in hematocrit to  $\sim 10.3\%$ . No changes in erythrocyte velocity were observed throughout the perturbation (Figure 4.11E). In Cap10, the baseline supply rate, velocity, and hematocrit were

measured at  $\sim 4.3 \pm 0.9$  RBC/sec, N=4,  $\sim 158.4 \pm 2.0$   $\mu\text{m}/\text{sec}$ , N=4, and  $\sim 15.3 \pm 0.3$  %, N=4, respectively. Increasing chamber  $\text{O}_2$  to 20% resulted in  $\sim 25\%$  decrease in supply rate and 11% decrease in hematocrit relative to baseline. The supply rate increased  $\sim 50$  following decrease in  $\text{SO}_2$  (at  $\sim 220$  sec) to slightly above baseline with a maximum of  $\sim 8.3$  RBC/sec which was also associated with increase in hematocrit to a maximum of  $\sim 18\%$  (Figure 4.11D,F). Increasing chamber  $\text{O}_2$  back to 20% resulted in sharp and instantaneous decrease in supply rate to a minimum of  $\sim 0.8$  RBC/sec and in hematocrit to a minimum of  $\sim 10\%$ . Decreasing chamber  $\text{O}_2$  level back to baseline resulted in supply rate increase to a maximum of  $\sim 3.5$  RBC/sec and in hematocrit to  $\sim 18\%$ . The erythrocyte velocity increased by 25% in response to low  $\text{O}_2$  in Cap10 but did not seem to change in response to high  $\text{O}_2$  (Figure 4.11E). In Cap11, the baseline supply rate, velocity, and hematocrit were measured at  $\sim 6.2 \pm 0.6$  RBC/sec, N=4,  $\sim 166.3 \pm 10.3$   $\mu\text{m}/\text{sec}$ , N=4, and  $\sim 12.8 \pm 0.6$  %, N=4, respectively. Increasing chamber  $\text{O}_2$  to 20% resulted in  $\sim 40\%$  decrease in supply rate and 32% decrease in hematocrit relative to baseline. The supply rate increased  $\sim 50$  sec following decrease in  $\text{SO}_2$  (at  $\sim 220$  seconds) to a maximum of  $\sim 6.8$  RBC/sec which was also associated with increase in hematocrit to a maximum of  $\sim 16.2\%$  (Figure 4.11D,F). Increasing chamber  $\text{O}_2$  back to 20% resulted in sharp and instantaneous decrease in supply rate to a minimum of  $\sim 3.5$  RBC/sec and in hematocrit to a minimum of  $\sim 10\%$ . Decreasing chamber  $\text{O}_2$  level back to baseline resulted in supply rate increase to a maximum of  $\sim 6.2$  RBC/sec, matching that at first baseline, and increase in hematocrit to  $\sim 17.4\%$ . No changes in erythrocyte velocity measured in Cap11 (Figure 4.11E).

(C)

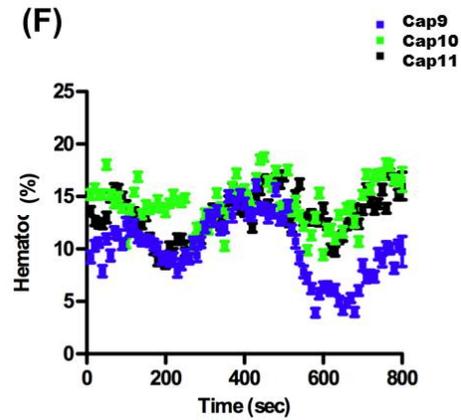

(D)

(E)

(F)

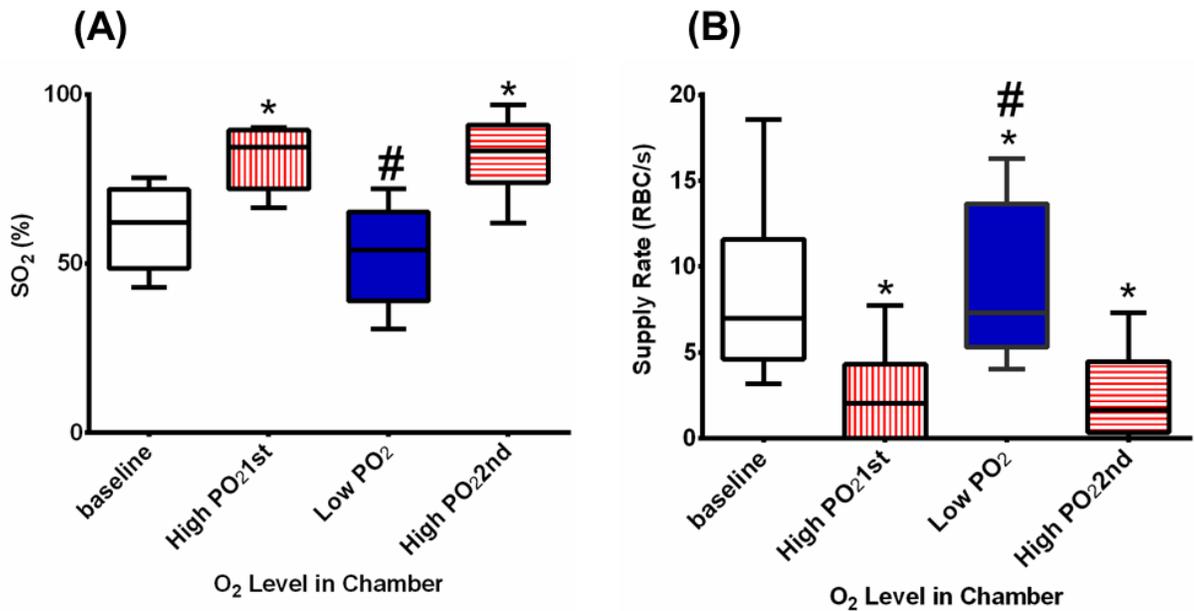

**Figure 4.11** Selected capillaries (Cap 9, 10, and 11) are positioned directly over the rectangular micro-slit (1000  $\mu\text{m}$  wide x 200  $\mu\text{m}$  long) outlined by white dashed line. (A) The feeding arteriolar end upstream of the selected capillary and flow direction are indicated. The three selected capillaries all drain into a venule positioned deeper in the tissue (B) Cap9, 10, 11 as visualised at 20X were analysed for changes in erythrocyte  $\text{SO}_2$  and supply rate. Capillaries were analysed for changes in erythrocyte  $\text{SO}_2$  (%), supply rate (RBC/sec), mean erythrocyte velocity ( $\mu\text{m}/\text{sec}$ ), and mean hematocrit (%) as  $\text{O}_2$  levels in the chamber are oscillated in two consecutive square waves (period  $\sim$  400 seconds). The tissue is equilibrated at 5% (38 mmHg  $\text{PO}_2$ )  $\text{O}_2$  level for 30 seconds. The  $\text{O}_2$  level in the chamber is increased to 20% ( $\sim$ 152 mmHg) then decreased to 2% ( $\sim$ 15.2 mmHg) for a 200 second then increased back to 20%. The chamber  $\text{O}_2$  level is then lowered back to baseline level (5%). An eight minute video sequence is captured beginning 2 min prior to the low  $\text{O}_2$  challenge. (C) The erythrocyte  $\text{SO}_2$  profiles in Cap 1, 2, and 3 are closely associated with chamber  $\text{O}_2$ . (D) Change in capillary  $\text{SO}_2$  result in supply rate responses. Supply rate changes seem to be more related to changes in (E) hematocrit rather than in (F) RBC velocity.

In order to determine if changes in capillary  $\text{SO}_2$  and supply rate in response to the  $\text{PO}_2$  perturbations are significant, the mean  $\text{SO}_2$  and supply rate ( $\pm$  standard error of the mean SEM) in all capillaries analyzed in this study were calculated and plotted against condition in chamber. The mean  $\text{SO}_2$  or supply rate levels at the various chamber  $\text{O}_2$  conditions were compared using a 2way analysis of variance test (ANOVA) with  $P < 0.05$  (Figure 4.12). The results indicated the mean capillary erythrocyte  $\text{SO}_2$  level during the low  $\text{O}_2$  challenge is not significantly different relative to baseline ( $P = 0.1062$ ) yet significantly different relative to the high  $\text{O}_2$  condition ( $P < 0.0001$ ). The corresponding mean supply rate level at low  $\text{O}_2$  is significantly different relative to both baseline and high  $\text{O}_2$  ( $P < 0.0001$ ). At high chamber  $\text{O}_2$  condition, both the mean capillary erythrocyte  $\text{SO}_2$  and supply rate levels are significantly different relative to baseline ( $P < 0.0001$ ) (Figure 4.12).

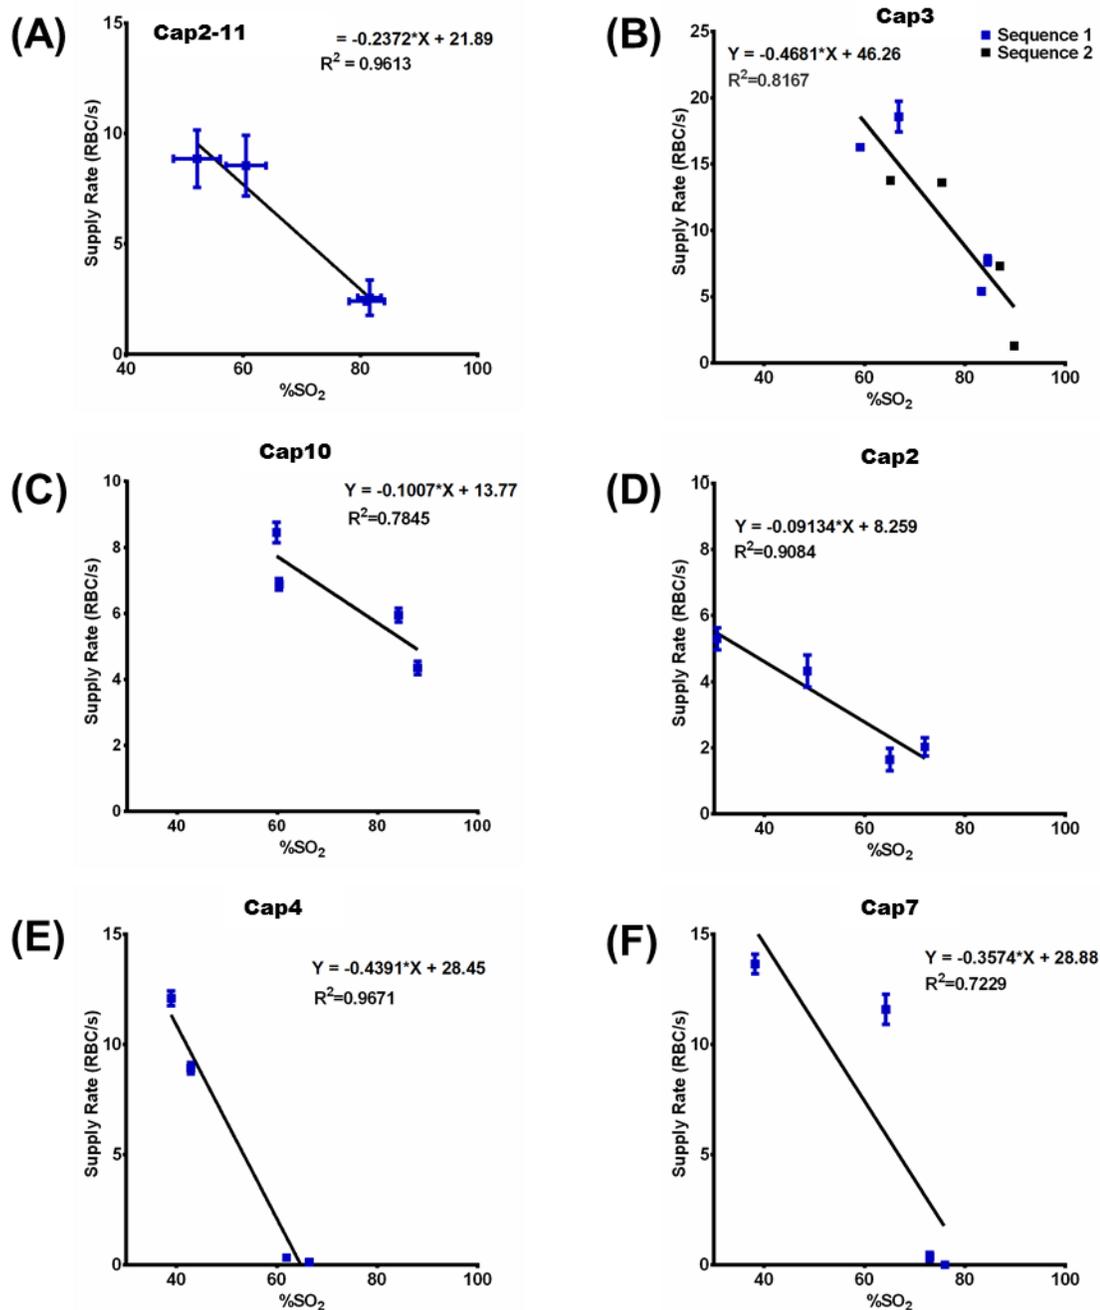

Finally, the correlation between mean capillary supply rate and erythrocyte  $\text{SO}_2$  in capillaries affected by the  $\text{PO}_2$  perturbations using the rectangular micro-slit design was tested. The mean supply rate levels calculated from all capillaries presented in this paper were plotted against corresponding mean  $\text{SO}_2$  levels. The mean data points ( $\pm$  SEM) were fitted using a linear regression function in Prism v 5.0 and the goodness of fit was assessed using the  $R^2$  value (Figure 4.13A). Also, the mean supply rate from individual representative capillaries analyzed in this study was plotted against corresponding  $\text{SO}_2$  and correlation was assessed (Figure 4.13B-F). In general, there seems to be a linear relationship between mean supply rate and erythrocyte  $\text{SO}_2$  level. Also, the slope of the

line of best fit seems to be related to the baseline supply rate level in the individual capillaries (Figure 4.13). There is a greater change in supply rate with change in  $\text{SO}_2$  in capillaries with higher baseline supply rate level. This suggests the strength of the conducted signal is related to the erythrocyte supply rate.

**Figure 4.12** (A) mean capillary  $\text{SO}_2 \pm \text{SEM}$  and (B) mean supply rate  $\pm \text{SEM}$  at different  $\text{O}_2$  conditions in chamber in a single  $\text{PO}_2$  perturbation: baseline  $\text{O}_2$  level (5%, 38 mmHg), first increase in  $\text{O}_2$  level (20%, 152 mmHg), low  $\text{O}_2$  level (2%, 15.2), second increase in  $\text{O}_2$  level (20%) (Recovery). At each  $\text{O}_2$  condition, the mean erythrocyte  $\text{SO}_2$  or supply rate values at the last 10 second time point in all capillaries presented in this study were used to calculate the overall  $\text{SO}_2$  or supply rate means. The means were compared using a 2way analysis of variance (ANOVA) ( $P < 0.05$ ) in Prism v 5.0. The symbol (\*) represents

means significantly different relative to baseline mean. The symbol (#) represents the case in which the mean at low O<sub>2</sub> condition is significantly different from the means at the high O<sub>2</sub> conditions. Mean capillary SO<sub>2</sub> ± SEM is significantly altered relative to baseline in response to high O<sub>2</sub> yet not to low O<sub>2</sub>. Corresponding mean capillary supply rates ± SEM levels at high and low O<sub>2</sub> are significantly different relative to baseline. The mean supply rate level at low O<sub>2</sub> is significantly different that at high O<sub>2</sub>.

**Figure 4.13** The correlation between mean capillary supply rate  $\pm$  SEM and mean  $\text{SO}_2$  measured from (A) all capillaries affected by the rectangular micro-slit in this study (Cap2-11) or (B-F) individual representative capillaries from each animal used in this

study (Cap2, 3, 4, 7, 10). The mean supply rate data points were fitted using a linear regression function in Prism v 5.0 and goodness of fit was assessed using an  $R^2$  value. There seems to be a linear relationship between measured mean supply rate and erythrocyte  $SO_2$ .

## 4.4 Discussion

The finding that erythrocytes have the ability to release signaling molecules in response to alterations in the micro-vascular  $O_2$  environment has transformed our perspective of the physiological role erythrocytes play (Ellsworth et al. 1995, Jia et al. 1996). Of special interest is the potent vasodilator, ATP, shown to be released from the erythrocyte in an  $SO_2$  dependent manner (Jagger et al. 2001) as well as in response to other stimuli (Bergfeld and Forrester 1992, Sprague et al 2006). ATP release from the erythrocyte under low  $SO_2$  conditions is proposed to trigger a conducted vasodilation (Ellsworth et al. 2009, Sprague and Ellsworth 2012). The micro-vascular response would be initiated by binding of ATP to  $P_{2y}$  receptors on the vascular endothelium resulting in conducted hyperpolarization in the endothelium and eventually in smooth muscle cells (You et al. 1999, Horiuchi et al. 2001, Sprague 2008, Ellsworth et al. 2009, Sprague and Ellsworth 2012, Ellis et al. 2012).

Multiple studies have examined the onset of conducted micro-vascular responses in the arterioles as well in the venules (Collins et al. 1998, Dulling and Berne, 1970, Duling, 1974, Jackson, 1987). Results have shown the capillary bed acts as a communication

medium through which the hyperpolarization signal would be conducted from the venules to upstream arterioles (Dietrich, 1989, Dietrich and Tyml, 1992a,b, Song and Tyml, 1993, Collins et al., 1998, Bagher and Segal, 2011). Since the largest  $\text{SO}_2$  drop takes place in the capillary bed, it has been suggested as a major site for  $\text{SO}_2$ -dependent ATP release by the erythrocytes (Ellis et al 2012). The relatively long erythrocyte transit time in the capillary and the short ATP diffusion distance from every erythrocyte passing through the capillary bed to the endothelium would ensure temporal and spatial localization of the signal (Ellis et al 2012).

In order to examine  $\text{SO}_2$ -dependent signaling in the capillary bed, we have developed a novel technique, an  $\text{O}_2$  micro-delivery system that allows for altering erythrocyte  $\text{SO}_2$  in a limited number of selected capillaries *in vivo* (Figure 4.1) (Ghonaim et al. 2011). Combining this technique with existing  $\text{D}\lambda\text{IVVM}$  technology allows for visualizing and measuring changes in blood flow parameters while simultaneously altering erythrocyte  $\text{SO}_2$ . Also, the extent of the  $\text{PO}_2$  perturbation in the tissue and its effect on total magnitude of ATP in a capillary network have been modeled using  $\text{O}_2$  exchange micro-outlets of various dimensions (Ghonaim et al. 2013). Our modelling data suggested there is a direct relationship between the number of capillaries affected by the  $\text{PO}_2$  perturbation and the total magnitude of capillary ATP (Ghonaim et al. 2013). This is probably related to the number of activated endothelial cells in the affected capillaries within a network (Ellis et al. 2012). The model shows that the circular micro-outlet (100  $\mu\text{m}$  in diameter) only affects one or two capillaries positioned directly above the micro-outlet and that the

change in capillary  $SO_2$  is quickly dissipated downstream from the micro-outlet. Since the length of the endothelial cell in skeletal muscle is  $\sim 104 \mu\text{m}$ , a small number of endothelial cells would be affected by changes in erythrocyte  $SO_2$  when using the circular micro-outlet. However, in the rectangular micro-slit ( $200 \mu\text{m}$  long  $\times 1000 \mu\text{m}$  wide), a larger number of capillaries are positioned above the micro-slit. Also, the  $PO_2$  perturbation is carried much further downstream and the re-oxygenation effect is less rapid since the impact of the outlet affects a broader area. Therefore, based on the modeling results, a rectangular micro-slit was proposed to allow for stimulating a larger number of endothelial cells which would result in a larger hyperpolarization signal that can be conducted upstream. This micro-slit design was also proposed to ensure capillaries surrounding the network of interest will experience the same  $PO_2$  drop when decreasing chamber  $O_2$ , which would minimize re-oxygenation and emphasize the response.

The  $PO_2$  perturbation regime used in this study to alter capillary erythrocyte  $SO_2$  involved a step change in chamber  $O_2$  from 5% baseline condition ( $38 \text{ mmHg } PO_2$ ) to 20% ( $152 \text{ mmHg}$ ). The chamber  $O_2$  level is then decreased for a low  $O_2$  challenge from 20% to 2% ( $15 \text{ mmHg}$ ) followed by recovery back to 20%. Physiologically, at higher chamber  $O_2$  level, the micro-slit would simulate a crossing arteriole acting as an  $O_2$  source to underlying capillaries, while at lower chamber  $O_2$  level, it would simulate a crossing venule acting to withdraw  $O_2$ . At the low  $O_2$  level, the  $PO_2$  ( $15 \text{ mmHg}$ ) is higher than the  $P_{50}$  ( $k$ ) values reported by Golub and Pittman (2012) ( $10.5 \pm 0.8 \text{ mmHg}$ ) and Wilson et al. (2012) ( $\sim 12 \text{ mmHg}$ ), hence, it is unlikely the tissue metabolism is altered

with the tested range of chamber O<sub>2</sub> values. Also, during the low O<sub>2</sub> challenge (15 mmHg), the narrow depth of the perturbation (Ghonaim et al. 2011, 2013) implies only the surface of muscle fibers at the tissue surface would be affected. This is supported by our statistical data, which indicate that erythrocytes do not sense significant changes in tissue PO<sub>2</sub> at low O<sub>2</sub> relative to baseline since measured SO<sub>2</sub> levels at the two respective conditions were not significantly different (P<0.05) (Figure 4.12). This allows us to examine the micro-vascular regulation mechanisms to altered PO<sub>2</sub> environments surrounding the capillaries without lowering PO<sub>2</sub> enough to disturb metabolic function. Finally, although alterations in tissue metabolism may result in the release of signaling molecules, no mechanism is yet elucidated that explains communication between muscle fibers and arterioles feeding a specific network of interest.

In this study, micro-vascular responses to altering SO<sub>2</sub> in multiple capillaries were examined *in vivo* using the rectangular O<sub>2</sub> micro-slit. The results were compared to the case in which a single capillary is positioned over a circular micro-outlet 100 μm in diameter (Figure 4.4). Although erythrocyte SO<sub>2</sub> could be altered in single capillaries crossing the circular micro-outlet, no corresponding supply rate responses were measured (Figure 4.4). This has been consistently observed when testing with the circular micro-outlet *in vivo* (data not shown). The observed time delay between chamber O<sub>2</sub> perturbations and capillary SO<sub>2</sub> changes would involve O<sub>2</sub> delivery time from the chamber O<sub>2</sub> inlet to tissue surface followed by the diffusion time into the capillary lumen and finally into the erythrocyte to bind hemoglobin. In capillaries upstream of slit, such

as the case with Cap4, the constant influx of erythrocytes with  $\text{SO}_2$  unaffected by the micro-slit would require a larger change in the surrounding tissue  $\text{PO}_2$  to show a marked effect on  $\text{SO}_2$ . This might explain the longer time delay measured for altering Cap4  $\text{SO}_2$  levels from the slit (Figure 4.7). The results indicate that in order to trigger supply rate changes in response to altered capillary  $\text{SO}_2$ , at least 3-4 capillaries in a branching network had to be affected by the  $\text{PO}_2$  perturbation using our larger micro-slit design (200  $\mu\text{m}$  long x 1000  $\mu\text{m}$  wide rectangular slit) (Figure 4.5-4.11). The results confirmed our modeling data (Ghonaim et al. 2013), indicating there is a threshold for the minimum number of capillaries that need to be stimulated by low  $\text{O}_2$  to elicit a micro-vascular response.

The results indicated there is a variable time delay from 10 to ~50-60 seconds in the supply rate response to low  $\text{PO}_2$ , while much shorter time delays were observed in the response to increased  $\text{SO}_2$  (Figure 4.5, 4.6, 4.9 and 4.11). *In vitro* measurements of ATP release rates provide estimates in the order of 150-500 msec (Dietrich et al. 2000, Wan et al. 2008), hence the dynamics of ATP release alone would not account for the long time delay observed. The response time to low  $\text{O}_2$  in the capillary would be dependent on other factors such as the time it takes to activate sufficient number of endothelial cells as well as on the geometry of the upstream arteriolar tree. At relatively higher supply rates, a single ATP releasing erythrocyte would activate a larger number of endothelial cells within a relatively shorter time (Ellis et al. 2012). On the other hand, slow moving erythrocytes will take longer to reach downstream endothelial cells (Ellis et al. 2012).

Our results show a dependence of the magnitude of the supply rate response on baseline supply rate in the capillary (prior to perturbation) (Figure 4.13). The calculated slope for the linear relationship between supply rate and  $\text{SO}_2$  was smaller in capillaries with lower baseline supply rate (Cap2,10) (Figure 4.13). Also, the signal for increased supply rate is not solely originating within the single capillary being analyzed; rather the entire network affected by the micro-outlet is contributing to the strength of the signal. Depending on the geometry of the arteriolar tree upstream of the capillary of interest as well as the distance to the feeding arteriole, a minimum threshold number of capillary endothelial cells may need to be activated to elicit effective vasodilation. Finally, depending on the branching of the upstream arteriolar tree, there would be some time delay in adjusting the erythrocyte distribution at bifurcations during vasodilation and for this altered hematocrit travel downstream to ensure capillary units with various  $\text{O}_2$  environments are receiving appropriate  $\text{O}_2$  supply.

All capillaries selected for analysis in this study were positioned such that the feeding arteriole is further than 50  $\mu\text{m}$  upstream of the micro-slit, which was modeled as the extent of radial  $\text{O}_2$  diffusion from the micro-slit (Ghonaim et al. 2011, 2013). Therefore, since in our experiments only capillaries are affected by the  $\text{PO}_2$  perturbations, the observed supply rate responses must be conducted to the upstream arterioles. This supports the hypothesis that micro-vascular signals are initiated and conducted from the capillary bed (Ellis et al. 2012). This is further strengthened by the observed reproducibility of the supply rate responses to altered capillary  $\text{SO}_2$  (Figure 4.6 and 4.7).

Also, there seems to be variation in the magnitude of the supply rate response between different affected capillary networks. This might be related to the number of affected capillaries draining from the same upstream arteriole. An arteriole with a larger number of downstream branching capillary networks positioned over the micro-slit is anticipated to experience a larger hyperpolarization signal (Figure 4.7 and 4.10). Two factors that contribute to supply rate responses would include increase in erythrocyte velocity due to vasodilation of upstream arterioles and the increase in hematocrit due to preferential erythrocyte distribution at upstream bifurcations. Our results indicate that the observed supply rate responses in the capillaries are more related to changes in hematocrit rather than velocity (Figure 4.11). This supports the preferential erythrocyte distribution as an important mechanism of O<sub>2</sub> regulation in the microvasculature.

The results clearly demonstrate that at low PO<sub>2</sub>, the O<sub>2</sub> regulation system is able to locally sense the decrease in erythrocyte SO<sub>2</sub> and to compensate for this altered O<sub>2</sub> environment by increasing the supply rate. According to our observations, the increase in supply rate results in a re-oxygenation effect by bringing larger number of O<sub>2</sub> carrying erythrocytes. Since the measured supply rate profiles are strongly associated with capillary erythrocyte SO<sub>2</sub> changes, we anticipate the response pathway involves the release of erythrocyte derived signaling molecules, most likely ATP. However, not only erythrocytes but also other cell types could be affected by the PO<sub>2</sub> perturbations in the selected capillary networks. It is unlikely that observed responses involve nerve stimulation since pentobarbital, which was used as the anesthetic throughout our

experiments, is known to severely suppress sympathetic nerve activity (Best et al. 1984). Further studies must be conducted to measure  $\text{SO}_2$ -dependent ATP release and more accurately assess its role in mediating observed micro-vascular responses.

One of the limitations in this study is the inability to resolve deeper tissue capillaries and hence measure their  $\text{SO}_2$  and supply rate changes to assess their possible contribution to the overall signal *in vivo*. Another limitation is that in our computational model of radial  $\text{O}_2$  diffusion from the micro-slit we do not take into account diffusion through the PDMS layer, which may increase the extent of radial diffusion. This might explain observing  $\text{SO}_2$  changes in Cap5 (Figure 4.9) situated outside of the micro-slit. The complexities of the  $\text{SO}_2$  mediated micro-vascular response demand analysis of  $\text{SO}_2$  and hemodynamics locally in a capillary of interest as well as globally in the surrounding micro-vascular geometry.

In conclusion,  $\text{SO}_2$ -dependent signalling in selected capillaries has been tested *in vivo* using the  $\text{O}_2$  micro-delivery system. The results indicated that capillaries are able to signal upstream arterioles for changes in supply rate in response to low  $\text{SO}_2$ . Also, there seems to be a threshold for the minimum number of capillaries that need to be stimulated by altered  $\text{SO}_2$  in order to elicit the conducted supply rate responses. The dependency of supply rate responses on changes in hematocrit supports preferential erythrocyte distribution at upstream bifurcations in  $\text{O}_2$  regulations. These findings provide valuable insight into  $\text{O}_2$  transport and its regulation both in health and disease. The increased diffusion distance of  $\text{O}_2$  in sepsis and the compromised vascular reactivity in Type-II

diabetes eventually lead to tissue hypoxia and organ failure (Goldman et al. 2004, Sprague et al. 2006; 2010). Understanding the fundamental mechanisms that govern O<sub>2</sub> regulation leads to the understanding of the pathophysiology underlying microvascular diseases. Further *in vitro* and *in vivo* work is needed to look at the dynamics of ATP release and its role in SO<sub>2</sub>-dependent signalling and regulation.

## Chapter 5

### 5 General Discussion

#### 5.1 Summary of results and conclusions

##### 5.1.1 Developing a technology for investigating SO<sub>2</sub> – dependent micro-vascular responses

In Chapter 2, we described an O<sub>2</sub> micro-delivery device developed for localized O<sub>2</sub> exchange to the micro-vascular bed (Ghonaim et al. 2011). This novel technology, which is based on the full gas exchange chamber setup (Jagger et al. 2005, Ellis et al. 2010; 2012, Ghonaim et al. 2011), allows for altering erythrocyte SO<sub>2</sub> in selected capillaries *in vivo*. Unlike the use of superfusion solutions for O<sub>2</sub> exchange from tissue (Duling 1974, Jackson and Duling 1983), our device delivers O<sub>2</sub> in a gas mixture. This ensures more effective diffusion of O<sub>2</sub> to the tissue and resolves the limitation of poor O<sub>2</sub> solubility in saline superfusion solutions. The use of micro-fabrication techniques to pattern O<sub>2</sub> exchange micro-outlets of desired dimensions is unique and versatile. Delivering O<sub>2</sub> from the micro-outlet to tissue surface in direct interface is more effective than traditional micro-pipetting technique employed for local delivery of substances. Both *in vitro* and *in vivo* testing as well as our modeling data indicate the radial diffusion away from the outlet is limited which better localizes and emphasizes of the signal (Ghonaim et al. 2011). In contrast, the use of micro-pipetting technique, also referred to as Pico-spritzing

(Riemann et al. 2010), results in tissue concentration of substances to be less than that in the pipette. Also, the delivery of substances in liquid form may result in washing away important signaling molecules from tissue surface. The results presented in Chapter 2 describe an effective and novel methodology that allowed for first time examination of micro-vascular responses emerging from the capillary bed due to highly localized stimulus.

### **5.1.2 Computational modeling of localized PO<sub>2</sub> perturbations on total ATP magnitude in a 3D capillary network**

Prior to examining micro-vascular response to altering erythrocyte SO<sub>2</sub> in selected capillaries using the O<sub>2</sub> exchange system, it was critical that we have initial predictions on the relationship between the number of affected capillaries and the magnitude of the SO<sub>2</sub>-dependent signal. Chapter 3 describes the development of a computational model to investigate the effect of limited O<sub>2</sub> exchange at the surface of a tissue with an idealized parallel capillary array on total ATP concentration (Ghonaim et al. 2013). Modeling local O<sub>2</sub> exchange through various sized micro-outlets indicated that a rectangular micro-slit (200 μm long x 1000 μm wide) has the optimal dimensions for altering hemoglobin SO<sub>2</sub> in sufficient number capillaries to generate effective changes in total [ATP]. These results suggested there is a threshold for the minimum number of capillaries that need to be stimulated *in vivo* by low tissue PO<sub>2</sub> to induce a conducted micro-vascular response. Modeling SO<sub>2</sub> changing in arterioles and their possible contribution to the net change in

[ATP] indicated the effect of the arteriole is minimal. However, the data also indicated the arterioles would act as O<sub>2</sub> sources thus influencing the O<sub>2</sub> distribution. The modeling data presented in Chapter 3 provide important insights into the use of our novel O<sub>2</sub> micro-delivery device in studying micro-vascular O<sub>2</sub> regulation in the capillaries *in vivo* (Ghonaim et al. 2013).

### **5.1.3 Examining SO<sub>2</sub>-dependent micro-vascular response using our developed technology *in vivo***

Chapter 4 investigated conducted micro-vascular signalling and response to varying SO<sub>2</sub> in selected capillaries on the micro-vascular bed *in vivo*. O<sub>2</sub> availability to specific capillary networks at the surface of muscle tissue (rat Extensor Digitorum Longus) was controlled using our novel O<sub>2</sub> micro-delivery approach. Based on our modelling data presented in Chapter 3 (Ghonaim et al. 2013), a rectangular micro-slit (1000 µm wide x 200 µm long) patterned in ultrathin glass/plastic sheet using state-of-the-art microfabrication techniques was used as the micro-outlet of optimal dimension for O<sub>2</sub> exchange. Combining our novel technology with existing dual wavelength *in vivo* video microscope (DλIVVM) techniques allowed for oscillating O<sub>2</sub> levels at tissue surface while simultaneously measuring and recording blood flow responses. Digitized video sequences were then processed for changes in capillary hemodynamic parameters and erythrocyte SO<sub>2</sub>. Our *in vivo* results confirmed our modelling data presented in chapter 3 and indicated there is a threshold for the minimum number of capillaries that need to be

stimulated by local  $PO_2$  perturbations in order to induce a conducted micro-vascular response. Although erythrocyte  $SO_2$  level can be measured in single capillaries flowing over an  $O_2$  micro-outlet down to 100  $\mu m$  in diameter, at least 3-4 capillaries need to be stimulated within a branching capillary network in order to induce a micro-vascular response. Micro-vascular responses originate from a capillary network positioned directly over the outlet with the feeding arteriolar end positioned upstream of the  $O_2$  micro-outlet, which suggests the responses are conducted. The results presented in chapter 4 indicate we have successfully designed an effective and novel tool for limiting  $O_2$  exchange to specific capillaries on the micro-vascular bed to understand fundamental mechanisms of micro-vascular  $O_2$  regulation.

By careful selection of the minimum  $PO_2$  in the chamber and using fixed levels of  $CO_2$  and temperature, the observed flow responses are due solely to the microvascular response to varying  $O_2$  levels and not to changes in tissue metabolism. Although the maximum  $PO_2$  in the chamber is higher than most tissues would experience, the resulting changes in erythrocyte  $SO_2$  in these capillaries are within the normal physiological range. Hence, the rectangular micro-outlet used in these studies does mimic a crossing arteriole or venule and does demonstrate that the capillary bed is capable of signaling its local  $O_2$  environment to the upstream arterioles to appropriately regulate  $O_2$  supply (Ellis et al. 2012).

## 5.2 Future Directions

The micro-delivery approach for localized O<sub>2</sub> exchange presented and verified in my thesis serves as promising tool for investigating the fundamental mechanisms for regulating micro-vascular O<sub>2</sub> supply. Our results support the hypothesis that capillaries are able to signal upstream arterioles for changes in erythrocyte supply rate in response to changes in capillary erythrocyte SO<sub>2</sub>. The strong relationship between erythrocyte SO<sub>2</sub> changes and supply rate supports the role of the erythrocyte in SO<sub>2</sub>-dependent release of signaling molecules. The next step would be to unravel the details of the signaling mechanisms mediating the observed vasomotor responses. The involvement of SO<sub>2</sub>-dependent ATP release and endothelium hyperpolarization could be indirectly examined using transgenic mice expressing Ca<sup>2+</sup> reporter genes in the capillary endothelium (Bagher et al. 2011). However, the possible role of other erythrocyte derived vasodilators as well as signalling from other cell types surrounding the capillaries of interest must also be examined. Currently, computational modelling and *in vitro* testing is conducted at Dr. Ellis' laboratory to investigate the dynamics of ATP release from erythrocyte due to low O<sub>2</sub> (Sove et al. 2013). The findings would elucidate the possible contribution of time scales involved in ATP release to the observed response delay to low O<sub>2</sub>. The use of transgenic mice would also help examine the association between the number of activated endothelial cells and the onset of supply rate responses by visualizing the Ca<sup>2+</sup> release *in vivo*.

The effectiveness of our novel micro-delivery system can be extended to allow for precise and accurate delivery of substances in liquid form (e.g. drugs) in addition to gaseous substances (e.g. O<sub>2</sub>, CO). In an *in vivo* experimental setup, in which substances are delivered to interfaced live tissue or cell culture, localized responses can be stimulated. The novel use of our micro-delivery system in conjunction with existing DLIVVM and analysis techniques would provide greater insight into the underlying physiological mechanisms in normal and disease models. The micro-delivery system is a versatile tool with wide range of applications. The system can be used to provide localized stimulus to tissue or cell culture *in vivo*. Also, the developed micro-delivery system could be modified to be used as a diagnostic tool. By placing sensor films over the micro-slit, biological fluids (e.g. plasma, blood, urine...etc) flowing through chamber could be assayed for the presence or release of certain substances.

## APPENDIX A

**AUP Number:** 2008-066-06

**PI Name:** Ellis, Christopher G

**AUP Title:** Characterization Of The Dynamics Of The Local O2 Regulatory System And Role Of The Red Blood Cell In Situ

**Approval Date:** 08/08/2012

**Official Notice of Animal Use Subcommittee (AUS) Approval:** Your new Animal Use Protocol (AUP) entitled "Characterization Of The Dynamics Of The Local O2 Regulatory System And Role Of The Red Blood Cell In Situ

" has been APPROVED by the Animal Use Subcommittee of the University Council on Animal Care. This approval, although valid for four years, and is subject to annual Protocol Renewal.2008-066-06::5

This AUP number must be indicated when ordering animals for this project.

Animals for other projects may not be ordered under this AUP number.

Purchases of animals other than through this system must be cleared through the ACVS office. Health certificates will be required.

The holder of this Animal Use Protocol is responsible to ensure that all associated safety components (biosafety, radiation safety, general laboratory safety) comply with institutional safety standards and have received all necessary approvals. Please consult directly with your institutional safety officers.

Submitted by: Copeman, Laura  
on behalf of the Animal Use Subcommittee  
University Council on Animal Care

Natural Sciences and Engineering Research Council of Canada  
(NSERC) Undergraduate Student Research Award (USRA)

May 2006-August 2006, May 2007-August 2007

Surface Science Western (SSW) best summer project award  
August 2006

**Related Work** Teaching Assistant

**Experience:** Western University

January 2009- May 2009, September 2009- December 2009

Student Research Fellowship

Western University, Department of Biochemistry

May2008 - August 2008

**Publications:**

Sove R.J., Ghonaim N.W., Goldman D., Ellis C.G. A Computational Model of a Microfluidic Device to Measure Oxygen-Dependent ATP Release from Erythrocytes. PLOS ONE. Manuscript submitted for publication. 2013.

Ghonaim N.W., Fraser G.M., Ellis C.G., Yang J., and Goldman D. (2013) Modeling steady state  $SO_2$ -dependent changes in capillary ATP concentration using novel  $O_2$  micro-delivery methods. *Frontiers in Physiology*. **4**:260

Ghonaim, N. W., Lau, W. M., Goldman, D., Ellis, C.G., and Yang, J. (2011) A micro-delivery approach for studying microvascular responses to localized oxygen delivery. *Microcirculation*. 18(8), 646-654

Nieradko, M., Ghonaim, N.W., Xi, L., Nie, H.-Y., Francis, J., Grizzi, O., Yeung, K.K.C., Lau, W.M. (2007) Primary ion fluence dependence in time-of-flight SIMS of a self-assembled monolayer of octadecylphosphonic acid molecules on mica discussion of static limit. *Canadian Journal of Chemistry*. 85(12), 1075–1082

Ghonaim, N.W., Nieradko, M., Xi, L., Nie, H.-Y., Francis, J.T., Grizzi, O., Yeung, K.K.C., and Lau, W.M. (2008). Primary ion fluence dependence in time-of-flight SIMS of self-assembled monolayer of alkyl thiol molecules on Au(111)—Discussion of static limit. *Applied Surface Science*. 255, 1029-1032

**Invited Talks:**

Ghonaim, N. W., Lau, W. M., Goldman, D., Ellis, C.G., and Yang, J. (2012) Local Oxygen Signaling: ATP and the Conducted Vasomotor Response. The 3rd Annual Smooth Muscle Underground Conference (SMUG). Westin Hotel, 400 West Broadway, San Diego, California. April 20, 2012 (International Meeting)

**Conference Presentations:**

Ghonaim, N. W., Lau, W. M., Goldman, D., Ellis, C.G., and Yang, J. (2012) Local Oxygen Signaling: ATP and the Conducted Vasomotor Response. Poster Presented at The Joint Meeting of the British Microcirculation Society and The Microcirculatory Society, Keble College, University of Oxford, Oxford, United Kingdom. July 4, 2012 (International Conference)

Ghonaim, N. W., Lau, W. M., Goldman, D., Ellis, C.G., and Yang, J. (2011) Conducted microvascular response to localized oxygen delivery using a novel micro-delivery approach. Poster Presented at The Joint Meeting of the European Society for Microcirculation (ESM) and the German Society of Microcirculation and Vascular

Biology (GfMVB), Ludwig-Maximilians-University, Munich, Germany. October 14, 2011 (International Conference)

Ghonaim, N. W., Lau, W. M., Goldman, D., Ellis, C.G., and Yang, J. (2010) Evaluating microvascular response to localized oxygen level variations by *in vivo* video microscopy. Poster Presented at The 9<sup>th</sup> World Congress for Microcirculation, Maison de la Chimie, Paris, France. September 27, 2010 (International Conference). Abstract published in *Microcirculation*.

Ghonaim, N. W., Lau, W. M., Goldman, D., Ellis, C.G., and Yang, J. (2009) Evaluating microvascular response to localized oxygen level variations by *in vivo* video microscopy. Poster Presented at The fall meeting of the Microcirculatory Society "Frontiers in Microcirculation: Control Processes and Clinical Applications", University of Missouri, Columbia, USA. October 17, 2009 (Regional Conference). Abstract published in *Microcirculation*.

Ghonaim, N.W., Nieradko, M., Xi, L., Nie, H.-Y., Francis, J.T., Grizzi, O., Yeung, K.K.C., and Lau, W.M. (2008) Primary ion fluence dependence in time-of-flight SIMS of self-assembled monolayer of alkyl thiol molecules on Au(111)—Discussion of static limit. Poster Presented at the Secondary Ion Mass Spectrometry (SIMS) XVI International Conference, Kanazawa, Japan. October 29, 2007.
