## Abstract

Effervescent atomization uses the internal gas-liquid mixture to produce spray. The behavior of two-phase flow inside the atomizer influences the spray characteristics and is dependent on the atomizer internal geometry and operating conditions. The present study is conducted in two parts; study of the bubble formation from a novel submerged nozzle in a liquid cross-flow and investigation of the internal and external two-phase flows in an effervescent atomizer.

The present study investigated the performance of a novel nozzle developed by Gadallah and Siddiqui (2013) in the liquid cross-flow. The impact of the nozzle shape, its configurations and orientations was experimentally investigated. The results showed that the novel nozzle generates smaller bubbles at higher detachment frequency for all cases compared to the standard nozzle. It is found that the rebound of the bubble from a side hole plays a key role in the early bubble detachment.

For the effervescent atomizer study, the influence of various operating and geometric parameters of the atomizer on the internal flow and spray droplet characteristics were studied along with a design improvement to the atomizer internal geometry. The results demonstrated that a conical base aerator tube and shorter mixing zone length provide more uniform bubbles in smaller size. A new type of bubble breaker was designed and tested in an effervescent atomizer. The results show that both internal and external two-phase flows in the atomizer were strongly influenced by bubble breaker configurations (diameter and number of holes). It was found that the liquid shear stress is the dominant force causing the bubble elongation and its eventual breakup.

## Keywords

Two-Phase flow; Novel nozzle; Effervescent atomizer; Liquid cross-flow; Bubbly flow; Spray droplets; Bubble breaker; High-speed imaging.

# Co-Authorship Statement

I hereby declare co-authorship in the chapters listed below:

## **Chapter 2:**

### **Bubble formation process from a novel nozzle design in a liquid cross-flow**

Authors: M. Hassanzadeh, K. Siddiqui, A. H. Gadallah, W. Chishty

Status: It has been submitted to International Journal of Multiphase Flow.

Experimental work and data analysis were performed by M. Hassanzadeh. A. H. Gadallah provided some consultation on the experimental design. The manuscript was written by M. Hassanzadeh and reviewed by K. Siddiqui, A. H. Gadallah and W. Chishty.

## **Chapter 3:**

### **Investigation of two-phase flow in an effervescent atomizer**

Authors: M. Hassanzadeh, K. Siddiqui, A. H. Gadallah, W. Chishty

Status: It will be submitted for publication.

Experimental work and data analysis were performed by M. Hassanzadeh. A. H. Gadallah provided some consultation on the experimental design. The manuscript was written by M. Hassanzadeh and reviewed by K. Siddiqui, A. H. Gadallah and W. Chishty.

## **Chapter 4:**

### **Effect of bubble breaker on the effervescent atomization process**

Authors: M. Hassanzadeh, K. Siddiqui, A. H. Gadallah, W. Chishty

Status: It will be submitted for publication.

Experimental work and data analysis were performed by M. Hassanzadeh. A. H. Gadallah provided some consultation on the experimental design. The manuscript was written by M. Hassanzadeh and reviewed by K. Siddiqui, A. H. Gadallah and W. Chishty.

## Preface

*“Research is to see what everybody else has seen and to think what nobody else has thought”*

*Albert Szent-Gyorgyi*

*To my parents and my husband*

## Acknowledgments

First and foremost, I would like to gratefully and sincerely thank my supervisor, Dr. Kamran Siddiqui for his inspiration, incomparable assistance and invaluable guidance. Without his guidance and persistence help this dissertation would not have been possible.

I would like to thank the National Research Council Canada (NRC), Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of the Western Ontario for the financial support. I would like to acknowledge the faculty and staff of Mechanical and Materials Engineering Department for their education and support. I would also like to thank all of my colleagues and friends for their assistance and encouragement.

I would like to express my sincere thanks to Dr. Alireza Daemi for his support during the past several years and helping me to develop my background in Fluid Mechanics.

My special thanks to my husband for his patience, encouragement and endless love. He was always there cheering me up and stood by me through the good times and bad.

Finally, the greatest thanks of all must go to my wonderful parents for their unconditional love and moral support. Words cannot express my gratitude for everything they have done for me. Although my time in Canada was not easy for them, they always supported me in my dreams and goals. I owe them everything in my life and I appreciate and love them more than words can say.

## 1 Atomizers

### 1.1 Introduction

Atomization of liquid into the spray is crucial in wide range of industrial processes such as; coating [1], spray drying, pharmaceutical [2, 3], chemical reactors [4, 5] and combustion [6]. There are different types of atomizers. Based on the required energy to form spray, the common atomizer types are categorized into pressure atomizer, rotary atomizer, electrostatic, ultrasonic atomizer or twin-fluid atomizer [7]. In an industrial application, the desired droplet size, the spray shape and the properties of the liquid are the key parameters to choose a specific type of atomizer [7].

In a pressure atomizer, the pressurized liquid is discharged from an orifice at high velocity. Due to the requirement of pressurized liquid, the pressure atomizers typically use low-viscosity liquids. This type of atomization has some limitations such as; large droplet size and low liquid flow rate [6]. In a rotary atomizer, a rotating surface is located in front of the liquid jet and the liquid spreads out and forms droplets due to the centrifugal force. In this type of atomizer, the external mechanical energy is required to rotate the surface. The electrostatic atomizers and ultrasonic atomizers utilize electrical and acoustic energies to produce spray. In ultrasonic atomizers, the ultrasound transducers are used to produce a resonance acoustic wave, which results in disintegration of the liquid jet and formation of the spray. In electrostatic atomizers, the liquid accelerated by an electrical charge results in a tiny liquid jet which further breaks into small-size droplet in small quantities [6, 7]. In twin-fluid atomizer, the kinetic energy of the pressurized gas used to interact with the liquid results in the liquid phase break up and formation of the spray. Twin-fluid atomizers usually use air as the driving fluid to produce spray. They are divided into air-blast, air-assist and effervescent atomizers. This type of atomizer has two subcategories based on the location of the two-phase flow

mixing; external mixing and internal mixing [6, 7, 8]. In air-blast and air-assist atomizers, air at very high velocity is introduced into already established jet or sheet of liquid before the exit orifice [6]. A basic limitation of these atomizers is the "low bubble growth rate", i.e. although the gas is the dissolved phase into the liquid, to enhance the spray quality, it is necessary for the gas phase to emerge from the liquid jet. To avoid this limitation, Lefebvre et al. [6, 9] designed an effervescent atomizer in which gas does not impart kinetic energy to the flowing liquid. In an effervescent atomizer, the low-velocity gas is injected into the liquid flow, upstream of the exit orifice and this injected gas in the form of bubbles inside the liquid provides a good atomization.

### 1.1.1 Effervescent atomizer

Among all conventional atomization techniques, effervescent atomization is known as a twin-fluid atomization. Effervescent atomization or "aerated-liquid atomization" was designed and developed by Lefebvre and his colleagues in 1980s and categorized into the internal two-phase flow mixing [9-12]. Compared to other forms of twin-fluid atomizer, effervescent atomizer uses low velocity gas injection into the liquid to form bubbly flow in the liquid stream. The gas-liquid mixture then moves downstream towards the exit orifice. The presence of bubbles inside the liquid flow enhances the atomization process by decreasing the fraction of the liquid passing through the exit orifice and by the expansion of the bubbles inside the liquid after ejection from the orifice. This expansion of bubbles forms thin ligaments and small droplets due to a sudden pressure drop [8].

There are several advantages for the effervescent atomizers over common atomizers. These include, excellent atomization at very low gas pressures, significantly smaller gas flow rates compared to those injected in the most forms of twin-fluid atomizers, and smaller drop sizes for any given injection pressure [6, 9, 11, 12]. The exit orifice diameters of the effervescent atomizers are larger in comparison with other types of atomizers at a similar flow rate [6, 10, 13-15]. The larger exit orifice mitigates the problems of clogging and hence, the atomization of impure liquids becomes possible [16, 17, 18]. Furthermore, for combustion applications, the air inside the liquid fuel enhances the combustion efficiency and reduces the pollutants such as NO<sub>x</sub> emissions [9, 16]. The

effervescent atomizer provides reliability and simplicity which results in easy maintenance and low cost [6].

Like other forms of twin-fluid atomizers, the effervescent atomizer also requires a source of pressurized gas, which is considered as its main drawback. However, this necessity can often be satisfied easily, since the effervescent atomization requires low gas pressure and low gas flow rate [8, 6]. Each effervescent atomizer, in terms of the gas injection configuration, is either "outside-in" or "inside-out". In the "outside-in" configuration, liquid stream flows inside a tube while gas is injected from the outside (i.e. peripheral region) into the liquid. Hence, the liquid flows in a large area due to the configuration of the gas injection [19]. This configuration has been well investigated previously [13, 18, 20-33]. The other gas configuration is "inside-out", in which gas is injected from aerator tube in the middle of the atomizer through the aeration holes into the liquid stream flowing in the peripheral region. While the "outside-in" configuration has a limitation of geometry change, the "inside-out" configuration is more flexible to geometry variation and allows changes in the dimensions of the atomizer components [34]. This configuration has also been studied by some researchers [12, 19, 34, 35, 36].

An inside-out effervescent atomizer is composed of gas and liquid inlets, mixing chamber, aerator tube and the exit orifice (see Figure 1-1). Each effervescent atomizer is also divided into different zones; bubble formation zone (or aeration zone) where the gas is bubbled into the liquid stream through aeration holes; the mixing zone where the bubbly-gas phase and the liquid phase are mixed, interact and flow downstream. The mixing zone includes parts of the atomizer, which are (i) the mixing chamber downstream of the aerator tube, (ii) the convergent section and (iii) the exit orifice. When the bubbles flow downstream, due to a pressure drop in the convergent section, the gas phase expands and if the length of exit orifice is large enough, the gas bubbles break up into smaller bubbles. After the ejection of gas-liquid mixture through the exit orifice due to a sudden pressure drop, bubbles (gas phase) further expand and thin liquid ligaments and small droplets are formed (see Figure 1-1) [8, 37]. This bubble expansion and breakup that occurs near the exit orifice is called the primary atomization. The unstable liquid droplets may collide, coalesce or further breakup in the turbulent spray after the

primary breakup. This further breakup of the droplets away from the exit orifice is called the secondary atomization [38]. Breakup is a process by which a bubble/droplet splits into two or more bubbles/droplets. Surface tension always acts to maintain the surface of the fluid particle stable while the shear forces acts to destroy it. Once the shear forces become large enough, the surface tension is no longer able to retain the gas-liquid interface stable and the breakup occurs [39].

In the bubble formation zone, gas is injected through the holes into the liquid cross-flow and forms bubbles. In relation to the effervescent atomization process, the formation of small-size bubbles in a large number is desirable. The liquid cross-flow has been reported to generate small bubbles [11, 12]. The number and size of aeration holes are also reported to have an effect on the bubble size and hence the spray droplet size [19, 40-42]. Wang et al. [12], Roesler and Lefebvre [11, 41] and Roesler [40] found that the droplet size distribution becomes narrower when an aerator tube with multiple holes is used instead of a single hole with a constant hole area. Whereas, Ghaemi [42] used porous media as an aerator tube and compared the results with that of the multi-hole aerator and found that the porous media produces smaller bubbles and improves spray stability. Few studies have used a perforated sheet (as a bubble breaker) located before the exit orifice of an effervescent atomizer and found that it reduces the droplet size and increases the droplet velocity [35, 43, 44]. However, none of them showed the effect of perforated sheet on the internal two-phase flow and the bubble breakup mechanism.

**Figure 1-1: Schematic of an effervescent atomizer and atomization process.**

As mentioned earlier, effervescent atomizer is an internal-mixing atomizer in which gas in the form of bubbles is mixed with the liquid. The two-phase flow regimes formed inside the atomizer could be bubbly flow, slug flow or annular flow [45]. The bubbly

flow is present at low gas to liquid flow rates ratio (GLR). As the GLR increases, the mixture regime changes to the slug flow and then to the annular flow. In the bubbly flow, the gas forms the discrete phase while the liquid is the continuous phase, i.e. bubbles are injected into the liquid and dispersed. In the bubbly flow, small individual or coalesced bubbles flow inside the liquid stream. With an increase in the GLR, the size of bubbles increase and reaches the size of the inner diameter of the mixing chamber whereby, the bubbly flow transforms into slug flow. With a further increase in the GLR, the gas flows in the center of mixing chamber surrounded by an annular film of liquid on the mixing chamber wall. Under such condition, the flow regime is considered as the annular flow. Figure 1-2 depicts these flow regimes inside the mixing zone of an effervescent atomizer.

**Figure 1-2: Three different flow regimes inside the effervescent atomizer (a) bubbly flow, (b) slug flow, (c) annular flow.**

The effervescent atomization process and consequently the characteristics of the resulting spray are dependent on the atomizer internal geometry [19, 30, 46] and GLR [19, 37, 47]. It has been reported that an increase in the GLR reduces the mean droplet size [19, 22,

47]. However, with an increase in the GLR, the internal flow changes from bubbly to slug flow, which increases the instability of the spray [18, 42]. The slug flow due to the presence of larger bubbles approaching the exit orifice causes significant spray pulsation and unsteadiness [18, 48], which is not desirable in the majority of industrial applications. Although the annular flow produces the smallest droplets, the requirement of the large volume of pressurized gas and unstable internal flow makes it not a preferable choice. Hence, the bubbly flow has been suggested as a better solution for a steady spray [47].

The internal mixture flow is dependent on the mixing zone cross-sectional area and the shape of the mixing zone [8, 19]. Furthermore, in the previous studies the effect of convergent angle [36], the exit orifice diameter [9, 17, 22, 32], the length of the exit orifice [36, 23] and the exit orifice shape [36, 29, 35] on the droplet size were investigated. Mostafa et al. [43] and Jedelsky et al. [30] reported that the mixing zone length affects the radial distribution of the spray droplet size and velocity while, Sher et al. [23] argued that the best mixing zone length for the effervescent atomization depends on the GLR.

### 1.1.2 Bubble formation in a liquid cross-flow

As mentioned earlier, the generation of small-size bubbles in large quantity is desirable for the effervescent atomization process and the bubble formation in a liquid cross-flow has shown to be an effective way to achieve this goal. Although the main focus of the present study is to investigate the dynamics of the internal and external two-phase flow in an effervescent atomizer, however, to gain a better insight into the fundamental bubble formation process in a liquid cross flow, the research has also been conducted to investigate the bubble formation and detachment process from a novel nozzle in a liquid cross-flow that in the future could potentially be used in the effervescent atomizer or other industrial applications.

The bubble formation through the gas injection into a liquid cross flow has several applications including effervescent atomization, chemical plants [49], waste water treatment and bio- and nuclear-reactors [50, 51]. In these applications, an important parameter is the total area of the gas-liquid interface, which influences the bubble

expansion in an effervescent atomizer or the reactivity and/or mass transport in chemical and biological processes. A larger total surface area of bubbles can be achieved by generating small-size bubbles at a higher detachment rate

Gas can be injected into a liquid stream in the co- or cross-flow configurations. Previous studies have shown that the liquid cross-flow generates smaller bubbles at a higher detachment rate compared to the liquid co-flow [52], which is likely due to a higher shear. The angular orientation, size and shape of the nozzle as well as the GLR influence the bubble formation and detachment process in a liquid cross-flow. Furthermore, in the cross-flow configuration, the chances of bubble coalescence are lower as compared to that in a stagnant liquid because the bubbles are continuously moved away from the surrounding area of the nozzle or orifice [53, 54]. Coalescence is the phenomenon in which two or more bubbles or droplets are combined through the contact surface to make a single bubble or droplet. Since the coalescence phenomenon increases the bubble diameter, the gas-liquid interface and the uniformity of bubbles distribution are reduced.

When the gas is injected into a liquid stream, the two-phase flow may result in one of the following forms;

- 1) Formation and advection of individual bubbles into the liquid stream, i.e. no coalescence and no mutual interactions (see Figure 1-3(a)).
- 2) Formation and advection of bubbles into the liquid stream that may interact and may result in coalescence (see Figure 1-3(b)).
- 3) The injection of gas into the liquid stream in the form of a jet i.e. no individual bubble formation (see Figure 1-3(c)) [16].

When the two-phase flow is comprised of individual and non-interacting bubbles, the bubbles are smaller in size and/or far apart from each other. As the gas flow rate increases, the bubble size increases and the individual bubbly flow regime is transitioned into the interacting bubbly regime. In this regime, bubbles could easily deform and the bubble collision and coalescence may also occur. A further increase in the gas flow rate results in the jet flow regime. Although no bubbles are formed at the orifice or nozzle, the

jet may breakdown into bubbles or ligaments further downstream. The above described two-phase flow regimes in the liquid cross-flow are illustrated in Figure 1-3.

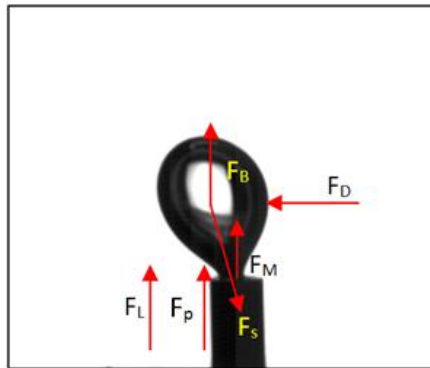

**Figure 1-3: Different flow regimes caused by injection of gas into a liquid stream. (a) Individual bubbly flow (b) Bubbly flow with bubble-bubble interaction (c) Jet flow.**

When the gas is injected into a liquid to generate bubbles, several forces act on the bubble. Figure 1-4 shows the main forces acting on the gas bubble during its growth and after detachment under these conditions. During the bubble growth, once the bubble is attached to the nozzle, these forces are, surface tension ( $F_s$ ), buoyancy ( $F_B$ ), gas momentum flux ( $F_M$ ), pressure ( $F_p$ ), inertial ( $F_I$ ), lift ( $F_L$ ) and drag forces ( $F_D$ ) [55]. However, once the bubble detaches from the nozzle the governing forces on the bubble reduce to buoyancy, lift and drag forces. The role of different forces is described as follows:

- The pressure force is caused by the difference between the gas pressure at the nozzle tip and the liquid pressure. This force acts in the upward direction during the bubble growth.
- The relative motion between the bubble and the liquid resulted in the exertion of friction force on the bubble as well as the net pressure force due to the change in the liquid pressure as it goes around the bubble. These forces have drag and lift

components in the direction parallel and perpendicular to the relative motion, respectively.

- Buoyancy force is generated due to the difference in the densities of gas and liquid. It acts in the upward direction and its magnitude increases with an increase in the bubble size. Hence, it contributes to the growth and detachment of the bubble.
- The role of the surface tension force is to keep the bubble attached to the nozzle. It has two components; the horizontal component acts against the liquid drag while the vertical component acts against the buoyancy force. As the bubble grows, the magnitude of the surface tension force increases.
- Inertial force also has two components in x and y direction. The growing bubble displaces and accelerates liquid surrounding the bubble which adds mass to the bubble [55].
- Gas momentum flux force through the nozzle is a detaching upward force and increases with an increase in the gas velocity or gas density.

(a)

(b)

**Figure 1-4: Governing force acting on the bubble (a) During formation, (b) After detachment.**

The bubble formation into the liquid cross-flow from a submerged gas injector has been studied experimentally, numerically and theoretically. Several parameters influence the bubble dynamics, which include, size, location and shape of the bubbles, their rate of detachment and the GLR. Several studies have investigated these parameters for example, the characterization of the bubble size [56-58], the bubble detachment frequency, the bubble trajectory in the liquid stream [59, 60], the bubble formation stages [57, 61] and the mode [62, 63], and the effects of gas flow rate and liquid velocity on the bubble formation [42, 55, 56, 58, 59, 64].

## 1.2 Motivation

As discussed earlier, effervescent atomizer has several advantages compared to other atomizers. However, due to the interaction of gas and liquid flows, the internal two-phase flow structure in the effervescent atomizer is more complex than that in single-fluid atomizers. Despite several studies, the flow inside an effervescent atomizer is not well understood. This is attributed to the complexities such as bubble-bubble interaction, gas-liquid mixing, gas-liquid flow through variable cross-sections and bubble deformation at

various locations inside the atomizer. Previous literature has shown that there is a strong dependence of the unsteadiness in the effervescent sprays on the atomizer internal two-phase flow. However, there is a lack of studies directly investigating the internal two-phase flow and its impact on the spray characteristics. Therefore, a thorough study of this internal two-phase flow, the parameters that control it and its relation with the spray characteristics such as droplet size is required to improve and control the spray quality.

The performance of the effervescent atomizer depends on the bubble formation inside the aeration zone, flow behaviour inside the mixing zone and the gas-liquid flow approaching the exit orifice. Hence, to optimize the effervescent atomization process, understanding of the two-phase flow dynamics in each section is crucial. Moreover, the study of a novel submerged nozzle in a liquid cross-flow and the investigation of the underlying physical process of bubble formation from it, would lead the potential utilization of this nozzle in an effervescent atomizer and other related applications.

### 1.3 Objective

Hence, the objectives of the present study are to:

- 1- Investigate the effect of a novel nozzle design on the dynamics and size of the bubbles inside a liquid cross-flow and explore the underlying phenomenon.
- 2- Improve understanding of the two-phase flow structure inside an effervescent atomizer and its characterization.
- 3- Quantify the relation between the atomizer internal two-phase flow and the spray characteristics.

The present study is based on an experimental research that is conducted using state-of-the-art measurement techniques. The methodology to meet the above listed objectives is described below.

To improve the knowledge of the bubble formation in an effervescent atomizer, first the impact of the nozzle configuration on the bubble formation in a liquid cross-flow is investigated using high speed imaging technique.

The same high speed imaging technique is used to study the influence of atomizer internal two-phase flow over a wide range of operating conditions to meet the second objective. The specific methodology includes:

- Detailed investigation of the mechanics of bubble formation from the holes of the aerator into a pressurized confined cross-flow. The specific focus is on the influence of aeration holes on the bubble size under different inlet conditions of gas and liquid flows.
- Detailed investigation of the two-phase flow regime, bubble deformation and bubble-bubble interaction inside the mixing zone. It includes bubble breakup using bubble breakers, and the final division into finer bubbles at the exit orifice. The flow regime inside the nozzle has a great influence on the spray behavior and the atomization process. The two-phase flow structure reaching the exit orifice has a direct influence on the near-nozzle liquid break-up and is a key feature that influences the spray characteristics. Thus, understanding the behavior of gas and liquid flow inside the mixing zone is crucial to understand and improve spray characteristics.

The third objective, which is focused on quantifying the relation between the atomizer internal two-phase flow and the spray characteristics, is essential for the performance improvement of the effervescent atomizer. This allows researchers to appropriately select the effervescent atomizer design parameters and the operating conditions that would lead to the desired spray characteristics. This objective is achieved by measuring the droplet size and velocity of the spray produced over a wide range of operating conditions using high speed imaging system.

## 1.4 Experimental measurement techniques

Different methods have been used in the past to investigate bubble formation inside the effervescent atomizer and to characterize spray droplets generated by the effervescent atomizers. Liu and Zheng [60] used Particle Image Velocimetry (PIV) technique to investigate the bubble behavior and surrounding liquid in a stagnant flow. Ghaemi et al. [42] applied Shadow-PIV/PTV technique to investigate the mechanism of bubble formation in a liquid cross-flow. They also used particle tracking velocimetry (PTV) and StereoPIV techniques to characterize spray droplets generated by the effervescent atomizer. High speed imaging system has also been used to study and quantify the bubble size inside the effervescent atomizer [37, 44, 47, 65, 66] and the spray shape and droplet breakup process [42, 66, 67]. Some studies have used phase-Doppler particle Analyzer (PDPA) to measure spray droplet size and velocity [19, 30, 47, 68]. It should be noted that both droplet diameter and velocity are important parameters to characterize a spray [42]. Among all the methods to measure the droplet velocity, an image-based technique provides more accurate results for the spray droplets particularly when the droplets are non-spherical in shape [69-72].

The high speed imaging technique used for bubble or droplet measurements often employed backlit shadowgraphy technique to enhance the signal-to-noise-ratio. In this technique, a light source along with a diffusion screen is placed behind the measurement region to provide a uniform brighter background in the image that corresponds to the liquid domain. This generates a good contrast between the bubbles and the background liquid hence makes the bubble identification easy and accurate. For example, Ghaemi [42], Sen et al [65] and Gadgile [66] have used diffused light source to illuminate the background along with high-speed imaging system to capture the images of the gas-liquid two-phase flow.

As mentioned earlier, the experiments in this research mainly involve the visualization and quantification of two-phase flow within a channel with liquid cross-flow, inside an effervescent atomizer, as well as the spray structures. The details of the state-of-the-art measurements techniques used in this research are provided below. The high-speed

imaging is conducted using a high-speed camera. This allowed tracking each individual bubble and droplet and quantifying various bubble and droplet characteristics. Backlit shadowgraphy with light source to illuminate the background was used during the experiments. The experiments were conducted for various configurations under different operating conditions and images were acquired at different sampling rates depending on the region of interest and the configuration.

#### 1.4.1 Bubble characteristics computation

The acquired images were processed using various in-house image analysis algorithms developed in the Matlab environment (for example see Siddiqui and Chishty [59]). The code automatically detects and tracks the bubble once it is detached from the nozzle, and computes various bubble characteristics such as the bubble trajectory in the liquid flow, detachment frequency, velocity, cross-sectional area and equivalent diameter. The main steps of the image-processing algorithm are step-by-step shown in Figure 1-5. A sample original image used as a reference is shown in Figure 1-5(a). The improvement of the signal-to-noise ratio is the first step of the image-processing algorithm, which is achieved by rescaling the gray-values based on the maxima and minima. The image is segmented into a binary image in the next step by applying a threshold based on the gray-value distribution. Figure 1-5(b) shows the corresponding image after segmentation. After image segmentation, a series of morphological operations are performed on the binary image that include image inversion, dilation, filling the holes and erosion, which are illustrated in Figures 1-5(c) and (d). The noise is removed in the next step, and in the final step, the bubbles chopped by the image edges are excluded (see Figures 1-5(e and f)) and each bubble is detected. For each detected bubble, different properties such as area, center of bubble, equivalent diameter and perimeter are calculated and stored in a three-dimensional array. To compute the detachment frequency, a different algorithm was used. In this algorithm, a region of interest was defined in the vicinity of the nozzle rim. The signal-to-noise ratio of the image was improved next. This is followed by the removal of noise. The algorithm continuously monitors the bubble while it is attached to the nozzle and records a signal as soon as the bubble detaches from the nozzle and

computes the equivalent bubble diameter. The recorded signal is used to compute bubble detachment frequency.

#### 1.4.2 Droplet characteristics computation

An in-house algorithm in the MATLAB environment was used to automatically detect and track the droplets and to quantify their characteristics such as droplet velocity, cross-sectional area, perimeter and corresponding equivalent diameter. The main steps of the image-processing algorithm are illustrated in Figure 1-6. A sample original image is shown in Figure 1-6(a). Similar to the bubble detection, the first step of the image processing is rescaling the gray-values based on the maxima and minima to improve the signal-to-noise ratio. In the next step, by applying a threshold based on the gray-value distribution the image is segmented into a binary image. Figure 1-6(b) illustrates image after adjustment and conversion into the binary image. Figure 1-6(c) and (d) show a series of morphological operations (image inversion, dilation, filling the holes and erosion) performed on the binary image. In the next step, the noise is removed (see Figure 1-6(e)). Then the droplets chopped by the image edges are excluded and hence only those droplets that are fully visible in the image are detected in the final step (see Figure 1-6(f)). Then different properties of droplets such as center of each droplet, cross-sectional area, equivalent diameter and perimeter are computed and the statistical data of the droplets was stored in a three-dimensional array. The x- and y-coordinate of the center of each bubble in two consecutive images was used to calculate the displacement of each droplet. The displacement of the droplet and the time interval between two consecutive images were used to compute the velocity of the each droplet. The data in the three-dimensional array was used to compute the droplets size and velocity in the form of mean and distribution.

## 1.5 Thesis layout

**First chapter** provides an introduction to the various atomization techniques and the fundamental foundation of the effervescent atomizer. The effervescent atomization technique with its main advantages and drawbacks are discussed. A short introduction of two-phase flow inside the effervescent atomizer and its effect on the atomization (spray) are also provided. Afterwards, to gain a better insight into the fundamental two-phase flow inside the effervescent atomizer, a brief introduction of bubble formation process in a liquid cross-flow is presented. Then the motivation and the objective of the present study are described. A brief description of the measurement and data processing techniques used in this study is provided at the end.

**Second chapter** investigates the process of bubble formation inside a liquid cross-flow from a novel submerged nozzle. A detailed study of the effect of gas and liquid flow rates and nozzle configuration on the process of bubble formation, bubble size and detachment frequency is provided. An image-base analysis is also used to describe and investigate the bubble formation and detachment process.

**Third chapter** focuses on the investigation of the atomization process in an effervescent atomizer. A detailed investigation of the two-phase flow behavior inside the atomizer under various atomizer internal geometries and operating conditions is presented. The impact of the internal flow on the spray droplet size and velocity is investigated next. These results are used to choose the optimal internal atomizer design for the forth chapter.

**Forth chapter** focuses on the investigation of the effervescent atomization process using a novel bubble breaker. A detailed discussion of the bubble fragmentation process using different type of bubble breakers inside the atomizer and the corresponding spray behavior is also provided.

**Fifth chapter** summarizes the conclusions of each chapter and presents an understanding of the two-phase flow in an effervescent atomizer and lists some future recommendations.

## Chapter 2

### 2 Bubble formation process from a novel nozzle design in a liquid cross-flow

#### 2.1 Introduction

Gas injection into a liquid stream and the dispersion of gas-liquid mixture into the spray have great importance in several industrial processes such as combustion [1, 2], food processing [3], metal casting [4], bubble column reactors [5, 6] and wastewater treatment [7]. In such applications, the gas-liquid interfacial area is a critical parameter, which affects chemical/biological reactivity of two phases as well as heat and mass transport. The larger surface area of gas bubbles per unit volume of liquid implies larger gas-liquid interfacial contact, which is achieved through smaller bubbles in numerous quantities than fewer large size bubbles. That is, the generation of smaller size bubbles at higher detachment frequency. The generation of smaller bubbles at higher detachment rate can be achieved by injecting the gas in the liquid cross-flow [8-14]. The liquid motion affects the bubble formation in two ways: (i) Flowing liquid induces drag force on the bubble attached to the gas injector. The shearing effect of the liquid drag force causes an early detachment of bubbles from the gas injector, which leads to the generation of smaller bubbles [11]. (ii) Flowing liquid also forces bubbles to move away from the gas injector reducing the possibility of bubbles' coalescence, which increases and randomizes the bubble size hence affects the bubble size distribution [12].

The injection of gas into a liquid stream may result in three regimes of two-phase flow: 1) flow of individual bubbles (no coalescence and no mutual interactions), 2) bubbly flow where bubbles could interact and may result in coalescence, 3) jet flow [15]. In individual bubbly flow, the bubbles are smaller in size and/or far apart from each other. An increase in the gas flow rate results in the transition of individual bubbly flow regime into the interacting bubbly regime. The bubble size in this regime is relatively large compared to

the individual bubbly regime and bubbles could easily deform. Furthermore, bubble collision and coalescence may also occur in this regime. This regime also is considered as a transition mode from the bubbly flow to the jet flow [15]. Eventually at very high gas flow rates, jet flow regime becomes dominant where a continuous jet of gas forms within the liquid stream. However, further downstream, this jet may break up into bubbles of different sizes [8, 16].

The bubble dynamics are characterized by many parameters such as, bubble size, detachment frequency, velocity, trajectory and formation mode. A number of computational and experimental studies have investigated the bubble formation in the liquid cross-flow. A large number of experimental studies utilized imaging techniques for bubble visualization [4, 8, 17-22]. Siddiqui and Chishty [19] experimentally studied the effect of channel orientation at various gas and liquid flow rates on the bubble detachment frequencies and trajectories. They conducted the experiments in a two-dimensional Plexiglas channel using high-speed imaging and image processing to investigate the effect of gas to liquid flow rates ratio (GLR) on the bubble detachment frequency. They also investigated the impact of channel inclination angle on the bubble trajectories. They observed that an increase in the channel inclination angle results in steeper bubble trajectories. They also found a linear relationship between bubble detachment frequency and GLR at low inclination angles of the channel which becomes nonlinear at higher inclination angles.

Ghaemi et al. [21] experimentally studied the influence of nozzle length on the bubble characteristics in a liquid cross-flow. They investigated the bubble size, shape, location and velocity at various gas and liquid flow rates for four injector lengths; one with zero length (i.e. a wall orifice) and the others with the nozzle length equal to 1, 2 and 3 mm of the channel dimension. They found that with an increase in the liquid flow rate, the bubble size decreased and detachment frequency increased. They also argued that at higher gas flow rates and lower liquid flow rates, the probability of coalescence occurrence increases. Marshal [5] experimentally investigated that three bubble formation modes appear in the liquid cross-flow: "single bubbling", "pulse bubbling" and "jetting". They also found that the bubble formation mode is influenced by gas and liquid velocity

and nozzle diameter. Tsuge and Hibino [23] studied the bubble formation in the liquid cross-flow both experimentally and theoretically. They used high-speed imaging and photo-transistor to detect the bubble detachment frequency. They investigated the influence of gas physical properties, orifice diameter and surrounding liquid velocity. They observed an increase in the bubble size with a reduction in the gas density. They concluded that at the constant operating conditions, the bubble size increases with an increase in the orifice diameter while higher liquid velocity produces smaller bubbles.

Nahra and Kamotani experimentally [18] and theoretically [24] investigated the effect of liquid cross-flow on the bubble formation. They conducted experiments under normal and reduced gravity and found that wall orifice diameter, gravity, liquid velocity and gas flow rates affect the bubble formation process. Bai and Tomas [4] numerically and experimentally studied the bubble formation from a wall orifice into the liquid cross-flow in a vertical channel. Volume of fluid (VOF) method and high-speed imaging were used for numerical simulation and experimental observation, respectively. They concluded that the gas compositions (air, helium and argon) and orifice diameter have relatively insignificant effects on the bubble size and that the bubble size reduces by increasing liquid velocity and/or decreasing gas flow rate. Forrester and Rielly [8] conducted an experiment study on the bubble formation from various shapes of submerged blades in liquid cross-flow and found that liquid cross-flow, gas velocity and blade shape influence the bubble size and bubble formation regime. Iguchi et al. [22] experimentally investigated the bubble detachment frequency for different nozzle diameters in a rotating water tank using high-speed imaging. Five nozzles with different inner and outer diameters were used during the experiments. They concluded that when the ratio of the outer to inner diameters of the nozzle was lower than 3.5, the outer diameter of the nozzle has a weak effect on the bubble detachment frequency.

As the above literature review shows, the bubble characteristics in liquid cross-flow have been extensively studied in the past. However, there is a scarcity of studies investigating the impact of the shape of the nozzle on the bubble formation in the liquid cross-flow. Recently, Gadallah and Siddiqui [25] developed a novel nozzle design that significantly increases the bubble detachment frequency and generates smaller bubbles. They tested

the nozzle in the stagnant liquid under various gas flow rates and observed that over a given range of gas flow rates, the novel nozzle increases the bubble detachment frequency by 58% and reduces the bubble diameter by 25%. The present study is focused on investigating the bubble formation process in a liquid cross-flow from this novel nozzle with some modifications, and studying the characteristics over a range of gas and liquid flow rates and comparing them with the standard nozzle.

## 2.2 Experimental setup

The experiments were conducted in a channel with square cross-section ( $5\text{ cm} \times 5\text{ cm}$ ), 100 cm long. Air and water were used as the gas and liquid mediums, respectively. The channel was made of acrylic. A honeycomb was placed near the upstream end of the channel to straighten the flow and remove flow disturbances. Water was circulated through the channel via a magnetic pump (Little Giant, 5 MD) from a 60 gallon reservoir (see Figure 2-1). Water flow rates were adjusted using a rotameter (FP 1-35-G-10/83, F&P Co) which was installed downstream of the pump. The pressurized air was injected into the liquid stream in the channel via a nozzle to generate bubbles. To maintain steady supply of air, the compressed air from the main supply line was first passed through a  $0.16\text{ m}^3$  tank, which served as a settling chamber, to remove pressure fluctuation. The air from the settling chamber then passed through a needle valve into a long capillary tube that was connected to the nozzle. The needle valve was used to control the air flow rate, which was measured by a rotameter located upstream of the needle valve (see Figure 2-1). The nozzle was located 70 cm downstream of the channel inlet. A prior set of experiments in the channel using Particle Image Velocimetry (PIV) technique confirmed that the channel flow was fully developed at the nozzle location. The uncertainties in liquid and gas flow rates based on the rotameters used were  $\pm 3$  and  $\pm 0.08\text{ cm}^3/\text{s}$ .

As mentioned earlier, a novel nozzle design developed by Gadallah and Siddiqui [25] was used in this study. The unique feature of this nozzle design was the presence of side holes near the main nozzle rim, which generates small bubbles with higher detachment frequency. Two side-holes nozzles are referred to as Configuration A. Two orientations of the novel nozzle were considered in the study. In the first orientation (I), the side holes

were aligned with the liquid flow direction and in the second orientation (II), the nozzle was rotated by  $90^\circ$  thus, the side holes were located perpendicular to the liquid flow direction, hereinafter referred to as Configuration A-I and A-II (see Figure 2-2). A standard nozzle was also considered which served as a reference case. Both novel and standard nozzles have inner diameter of 0.82 mm and outer diameter of 1.62 mm and were made from brass tube. Three diameters of the side-holes were considered in this study, which were 0.5, 0.7 and 0.82 mm. Experiments were conducted at four liquid flow rates and three gas flow rates for each nozzle. Table 2-1 summarizes the gas and liquid flow rates and the corresponding velocities.

A high-speed camera (Photron SA5) with a 60 mm lens was used to capture bubble image. The camera has the resolution of  $1000 \times 1000$  pixels up to 7500 frames per second. The camera resolution decreases with a further increase in the frame rate. The camera was connected to a PC and was operated via Photron FASTCAM Viewer software. The camera has a built-in memory card that allowed direct image recording. These images were later transferred to the hard drive. Back-lit shadowgraphy technique was used to illuminate the background for bubble identification. For this purpose, a 500 W halogen lamp was placed behind a diffusion screen to generate a uniform light. The images were captured at a rate of 1000 frames per second, and 2500 images were acquired and processed for each case. An in-house Matlab algorithm developed by Siddiqui and Chishty [19] was used to detect bubbles and to quantify various bubble parameters. Once a bubble is detached from the nozzle, the code automatically detects and tracks the bubbles and computes various bubble characteristics such as the bubble trajectory, detachment frequency, velocity, cross-sectional area and equivalent diameter. The uncertainty of detecting the bubble boundaries was within  $\pm 2$  pixels, which correspond to the uncertainty of  $\pm 0.06$  mm that translated into bubble diameter uncertainty of  $\pm 0.13$  mm.

The experimental procedure used in this study is described as follows. The first set of experiments was conducted for stagnant liquid and varied the gas flow rates from 0.168 to  $0.522 \text{ cm}^3/\text{s}$ , as mentioned earlier (see Table 2-1). In the following sets of experiments, the liquid flow rate was set and for the given liquid flow rate, the gas flow rate changed

from a minimum to a maximum value. At each condition, the image acquisition started 10 minutes after setting the gas flow rate to reach the steady state.

To visualize the bubble formation and detachment mechanism and to study the gas behavior inside and outside the nozzle during bubble formation, a second set of the experiments was conducted using glass nozzles. Both standard and novel nozzles were made from glass tubes with inner and outer diameters of 0.99 mm and 1.28 mm, respectively. The novel nozzle had a side-hole diameter of 0.86 mm. Due to the difficulty in exactly matching the diameters of commercially available brass and glass tubes, the glass nozzles has slightly different dimensions compared to the brass tubes. However, they served the purpose of visualizing the underlying phenomenon. For the glass nozzle study, the experiments were conducted at the same liquid flow rates described earlier and one gas flow rate ( $0.881\text{ cm}^3/\text{s}$ ). To accurately capture the underlying phenomenon, the frame rate for the glass nozzle experiments was set at 10,000 frames per second. At each condition, the image acquisition started 20 minutes after setting the liquid flow rate to reach the steady state. For each case, 5,000 images were acquired.

## 2.3 Results and Discussion

In the present study, the bubble formation was investigated during vertical gas injection through a submerged nozzle into a cross-flowing liquid stream. Figure 2-3 shows the main forces acting on the gas bubble during its growth and after detachment under these conditions. During the bubble growth, once the bubble is attached to the nozzle, these forces are, surface tension ( $F_s$ ), buoyancy ( $F_B$ ), gas momentum flux ( $F_M$ ), pressure ( $F_p$ ), inertial ( $F_I$ ), lift ( $F_L$ ) and drag forces ( $F_D$ ) [18, 24]. However, once the bubble detaches from the nozzle the governing forces on the bubble reduce to buoyancy, lift and drag forces. The role of different forces is described as follows:

- Difference between the gas pressure at the nozzle tip and the liquid pressure causes an upward pressure force on the growing bubble.
- The relative motion between the bubble and the liquid resulted in the exertion of friction force on the bubble as well as the net pressure force due to the change in the liquid pressure as it goes around the bubble. These forces have drag and lift components in the direction parallel and perpendicular to the relative motion, respectively.
- Buoyancy force is the upward force, which promotes bubble growth and detachment. The magnitude of this force also increases with an increase in the bubble size.
- Surface tension force has two components, both of which act to keep the bubble attached to the nozzle. The horizontal component acts against the liquid drag while the vertical component acts against the buoyancy force. The surface tension force increases with the bubble growth and deformation.
- Inertial force also has two components in x and y directions. The growing bubble displaces and accelerates liquid surrounding the bubble, which adds mass to the bubble [18].
- Gas momentum flux force through the nozzle is a detaching upward force and increases with an increase in the gas velocity or gas density.

(a)

(b)

**Figure 2-3: Governing force acting on the bubble (a) During formation, (b) After detachment.**

In the present study the bubble formation were investigated during vertical gas injection through a submerged nozzle into a cross-flowing liquid stream. The bubble formation from the standard nozzle in the liquid cross-flow occurs in two stages. When gas injects through the nozzle, bubble starts to grow. At this growing stage, since the bubble size is small, the drag force induced by the liquid cross-flow is negligible. The shape of bubble at this stage is assumed to be spherical. In the second stage or elongation stage, the bubble is still growing and attached to the nozzle but the shearing effect from the liquid cross-flow due to the friction drag elongates the bubble in the liquid flow direction [4].

Figure 2-4 shows the bubble detachment frequency ( $f_B$ ) as a function of the average liquid velocity ( $V_L$ ), for the standard nozzle at three gas flow rates. These results show the dependency of bubble detachment frequency on the gas flow rate. As expected, at a given gas velocity, the detachment frequency increased with an increase in the liquid velocity and at a given liquid velocity, the detachment frequency increased with an increase in the gas flow rate. As mentioned earlier, the drag force induced by the liquid cross-flow pushes the bubbles to move away from the nozzle. Thus, the rate of bubble detachment increases with an increase in the liquid velocity due to the increase in the drag force. Similarly, as the gas flow rate increases, the bubble grows faster and hence the buoyancy force pushes the bubble up. This rapid growth of bubble also increases the liquid drag force. Both of these forces lead to the bubble detachment.

**Figure 2-4: Bubble detachment frequency ( $f_B$ ) versus average liquid velocity ( $V_L$ ) for the standard nozzle at three different gas flow rates. Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

Figure 2-5 compares the bubble detachment frequency of all nozzles as a function of liquid velocity at the gas velocity of 31.84 cm/s. The results clearly show that the bubble detachment frequency significantly enhances using the novel nozzle design. For the standard nozzle at a given gas flow rate, an increase in liquid flow rate causes an increase in the bubble detachment frequency. However, for the novel nozzle at the given side-hole diameter used in this study, the liquid flow rates have a weak effect on the bubble detachment frequency. This shows some clear advantages of novel nozzle particularly at lower liquid flow rates because for the standard nozzle, the detachment frequency decreases with a decrease in the liquid flow rate, whereas for the novel nozzle it still maintains high detachment rate. For example, at the lowest liquid flow rate, the bubble detachment frequency of the novel nozzle is 2-3 times higher than that of the standard nozzle. This difference decreases with an increase in the liquid velocity and becomes almost negligible at the highest liquid velocity. It is also observed that the bubble detachment frequency is a function of the side-hole diameter. The results show that with an increase in the size of the side-hole, the bubble detachment frequency increased at first and then decreased. This trend specifies that the bubble detachment frequency could be maximized with an optimal side-hole diameter.

**Figure 2-5: Bubble detachment frequency ( $f_B$ ) versus average liquid velocity ( $V_L$ ) at gas velocity of 31.84 (cm/s). Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

Figure 2-6 shows the impact of new nozzle design and its orientation on the bubble diameter as a function of liquid velocity at a gas velocity of 31.84 cm/s. Note that the bubble diameter was measured immediately after its detachment from the nozzle since the bubbles are approximately spherical at that stage. The results from the standard nozzle are also plotted for comparison. For the standard nozzle, as expected, the results show a monotonic decrease in the bubble diameter with an increase in the liquid velocity, at a given gas velocity. The results for the novel nozzle show no dependency of the bubble diameter on the liquid velocities at any orientation. In addition, the novel nozzle produced smaller bubbles than that generated by the standard nozzle. This difference decreased with an increase in the liquid velocity, similar to that observed for the bubble

detachment frequency (see Figure 2-5). In the stagnant liquid, the bubbles generated by the novel nozzle were on average 30% smaller than those generated by the standard nozzle. This difference reduced to about 8% at the highest liquid velocity. The results also show the bubble size decreased with an increase in the side-hole diameter for both orientations of the novel nozzle. This difference however, reduced with an increase in the liquid velocity. For example, in the stagnant liquid, the size of the bubble generated by nozzle with 0.82 mm diameter side-hole was about 15% and 11% smaller than that from the 0.5 mm diameter side-hole for perpendicular and inflow orientations, respectively. This difference reduced to 1% and 8%, respectively, at the highest liquid velocity. Furthermore, the results also indicate that there is no significant effect of the nozzle orientation on the bubble diameter. The results in Figure 2-6 are presented for one gas velocity, similar trends were observed at other gas velocities (not shown here).

The results in Figure 2-5 and 2-6 demonstrate that the novel nozzle with the side-holes generated smaller bubbles with higher detachment frequency compared to that of the standard nozzle over a range of liquid velocities. The results also show that for the novel nozzle, both the bubble diameter and the detachment frequency are not dependent on the liquid velocity, unlike the standard nozzle, in which both of these parameters are heavily dependent on the liquid velocity. Both the bubble diameter and the bubble detachment frequency play an important role in the effective interaction of liquid and gas phases. Smaller bubbles in large numbers are desirable in applications involving gas-liquid reactivity as they increase the overall surface area of the gas-liquid interface. Based on the above results, we can conclude that the novel nozzle has substantially better performance than the standard nozzle especially at low liquid velocities or in the stagnant liquid.

**Figure 2-6: Bubble diameter ( $D_B$ ) versus average liquid velocity ( $V_L$ ) at a gas flow rate of 31.84 (cm/s). Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

Figure 2-7 shows the bubble detachment frequency as a function of gas velocity at a constant liquid velocity of 9.85 cm/s. The plot shows that the detachment frequency increased with an increase in the gas velocity for all nozzles and orientations. It is also observed that at a given gas velocity, the detachment frequency of the novel nozzle is substantially higher than that for the standard nozzle. On average, the bubble detachment frequency from the novel nozzle was 2.5 times higher than the standard nozzle. The results also show that the increase in the detachment frequency with the gas velocity is more rapid for the novel nozzle (i.e. steeper slope) compared to the standard nozzle. Figure 2-7 however, did not show a monotonic change in the detachment frequency with the side-hole diameter. That is, the detachment frequency first increased when the side-

hole diameter was increased from 0.5 mm to 0.7 mm and then decreased with a further increase in the side-hole diameter. The nozzle orientation did not show a distinct trend for the bubble detachment frequency.

**Figure 2-7: Bubble detachment frequency ( $f_B$ ) versus average gas velocity ( $V_g$ ) at a liquid velocity of 9.85 (cm/s). Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

The change in the bubble diameter as a function of gas velocity is shown in Figure 2-8 at a constant liquid velocity of 9.85 cm/s. The results show that at a given liquid velocity, the bubble diameter increased with an increase in the gas velocity, as expected. Comparison shows that the rate of increase in the bubble diameter with respect to the gas velocity is in general, comparable for both standard and novel nozzles, however, at a given gas velocity, the bubble diameter is on average, 30% smaller than the standard nozzle. The change in the side-hole diameter as well as the nozzle orientation did not

show a clear trend on the bubble diameter. The results in Figure 2-8 are presented for one liquid velocity, similar trends were observed at other liquid velocities and for the stagnant liquid (not shown here).

**Figure 2-8: Bubble diameter ( $D_B$ ) versus gas velocity ( $V_g$ ) at a liquid velocity of 9.85 (cm/s). Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

The results in Figures 2-7 and 2-8 are presented for specific gas and liquid velocities to investigate the trends of bubble detachment frequency and bubble diameter by varying either the liquid velocity or the gas velocity. To present the general trends, the bubble detachment frequency and flow rates are expressed in non-dimensional forms in terms of the Strouhal number ( $St$ ) and the gas to liquid flow rates ratio (GLR), respectively. The

Strouhal number, based on the inner diameter of the nozzle ( $D_N$ ) and the average liquid velocity ( $V_L$ ) is defined as,

$$St = f_B D_N / V_L \quad (1)$$

Where  $f_B$  is the bubble detachment frequency. The results are presented in Figure 2-9. The results show that in general, the Strouhal number increased with an increase in GLR. The results clearly distinct the Strouhal number trend for the novel nozzle from that of the standard nozzle i.e. the Strouhal number for the novel nozzle, increased more rapidly with GLR compared to the standard nozzle. Furthermore, the Strouhal number values for the novel nozzle are in general higher than the standard nozzle and this difference increased with an increase in the GLR.

**Figure 2-9: Strouhal number (St) versus GLR. Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

Figure 2-10 presents the relationship between the bubble diameter and the flow rates in a non-dimensional form, which shows a general trend of increasing bubble diameter with GLR. The bubbles generated from the novel nozzle were in general, smaller than that generated from the standard nozzle.

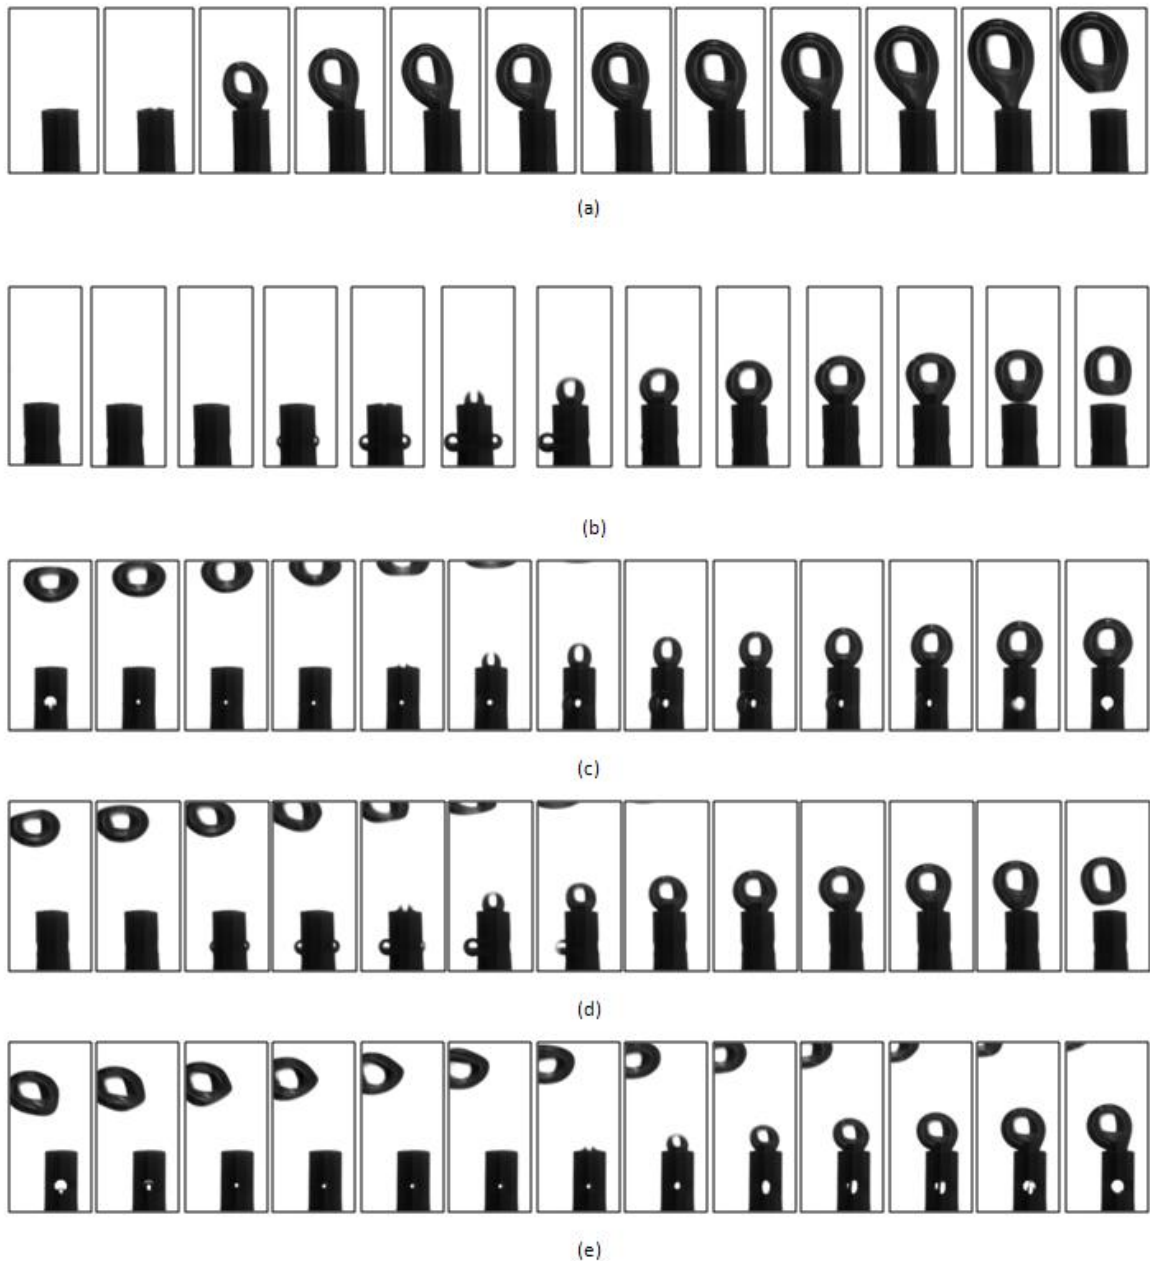

**Figure 2-10: Mean bubble diameter to inner nozzle diameter ratio ( $D_B/D_N$ ) versus gas to liquid flow rate ratio (GLR). Error bars are (based on standard error of the mean) smaller than the size of bullets.**

### 2.3.1 Bubble detachment mechanism

The results in the preceding section provide clear evidence that the novel nozzle with side-holes generate smaller and numerous bubbles than the standard nozzle in a liquid cross-flow under a very wide range of operating conditions. In this section, the underlying mechanism that led to the formation of smaller bubbles at higher rate will be discussed. The image sequences captured to quantify bubble size and detachment frequency can be used to qualitatively describe the bubble formation process from the novel nozzle.

Image sequences showing the bubble formation and detachment process from the standard and novel nozzle for two side-hole orientations are illustrated in Figure 2-11. The images for the standard nozzle (Figure 2-11(a)) show the classical behavior of the bubble formation as described earlier. Figure 2-11(b) and (c) show the bubble formation process from the novel nozzle in stagnant liquid showing the side-holes from two perpendicular angles. It is observed that the presence of the side-holes in novel design affects the bubble generation process. Figures show that after the detachment of the previous bubble, once the gas reaches to the side-holes, it expands through side-holes first. Once gas expands through the side-hole, gas-liquid interface stretches and stores energy. This stored energy increases, since the gas continues to expand through the side-holes. This stage is considered as the expansion stage. During the expansion stage, the gas also expands through the main nozzle hole. When the bubble size increases, at a certain stage, the buoyancy force becomes large enough to push the growing bubble. Furthermore, the higher liquid hydrostatic pressure force at the side-holes pushes back the gas into the nozzle. Meanwhile, the stored energy in the gas-liquid interface converts into kinetic energy of gas which further supports this push back. This stage is considered as the collapse stage. The dynamic motion of the gas volume shown in collapse stage is referred to the “gas-liquid interface motion”. Similar to the elasticity of a solid material, which tends to return a defamed shape to the original shape, surface tension tends to maintain the bubble-liquid interface stable. The push back of the gas into the nozzle due to the combined effect of the interface motion and the liquid hydrostatic pressure force, leads to the shearing of the gas volume inside the nozzle. Ultimately, this shearing effect

results in an earlier bubble detachment considered as the pinch-off stage. This consequently results in the formation of smaller bubbles at higher frequency. Figure 2-11(d) and (e) shows the effect of cross-flow on the bubble formation process for the novel nozzle with side-holes oriented in-line and perpendicular to the liquid flow, respectively. A quick comparison between Figure 2-11(d) and (b) shows that due to the effect of drag force from cross-flowing liquid, the expansion stage changes to collapse stage earlier than that in the stagnant liquid and the size of windward bubble decreases. Therefore, an increase in the liquid velocity hence an increase in the drag force results in a decrease in the gas-liquid interface rebound force due to a decrease in the stored potential energy in the smaller windward bubble. Thereby with an increase in the liquid velocity, the combined effect of the liquid drag force and the rebound force remains almost the same. Therefore, the novel nozzle shows almost no dependency of the liquid velocity on the bubble characteristics. The shearing effect inside the nozzle is clearly evident in Figure 2-11(e) which shows the undisturbed view of the side-hole. Note that this shearing effect is caused solely due to the presence of the side-holes.

**Figure 2-11: Image sequences showing the effect of liquid cross-flow on the dynamic gas-liquid interface motion during bubble formation from the novel nozzle with side-hole diameter of 0.7 mm at a gas flow rate of 0.28 cm<sup>3</sup>/s. (a) Standard nozzle at liquid flow rate of 255 cm<sup>3</sup>/s ( $\Delta t=4\text{ms}$ ). (b), (c) Novel nozzle in-line and perpendicular orientation at stagnant liquid flow ( $\Delta t=1\text{ms}$ ). (d), (e) Novel nozzle in-line and perpendicular orientation at liquid flow rate of 255 cm<sup>3</sup>/s ( $\Delta t=1\text{ms}$ ).**

Results in Figure 2-12 show that the size of the side-hole has an impact on the bubble diameter and detachment frequency. However, there was not a specific trend over the entire range of GLRs considered. We further investigated this issue to obtain a better understanding for this variation in the trend. The results are presented in Figure 2-12 which illustrates the bubble formation and detachment process from nozzles with different side-hole diameters. It is observed that for the case with the smallest side-hole diameter, the bubbles are always formed and detached from the main top nozzle. While by increasing the side-hole diameter to 0.82 mm bubbles are always formed and detached from side-holes.

**Figure 2-12: Image sequences showing the bubble formation from different side-hole diameters of in-line novel nozzle at a gas flow rate of  $0.168 \text{ cm}^3/\text{s}$  and liquid velocity of  $9.85 \text{ cm/s}$  (a) novel nozzle with side-hole of  $0.5 \text{ mm}$  ( $\Delta t = 5 \text{ ms}$ ), (b) novel nozzle with side-hole of  $0.7 \text{ mm}$  ( $\Delta t = 4 \text{ ms}$ ) and (c) novel nozzle with side-hole of  $0.82 \text{ mm}$  ( $\Delta t = 4 \text{ ms}$ ). The liquid stream is from right to left.**

### 2.3.2 Glass nozzle

The image sequences shown earlier in Figures 2-11 provide a good perception about the overall bubble formation and detachment process from the novel nozzle design compared to the standard nozzle. The results indicate that the gas at the side-hole undergoes expansion and collapse stages resulting in a gas-liquid interface motion, which eventually pinches off the gas in the nozzle leading to the early bubble detachment. This process of expansion, collapse and pinch off is the key for the higher detachment rate and hence the smaller bubble size. Due to the opaque nature of the brass tube used as nozzles, the crucial stages of collapse and pinch off are not clearly visible. To get a better insight into this process, both standard and novel nozzles from glass tube were manufactured and used to study this process. As mentioned in the experimental setup section, due to the mismatch in the internal diameter of commercially available glass and brass tubes, the internal and side-holes diameters of glass nozzles were slightly different from the brass nozzle (see experimental setup section for details). Consequently, the gas flow rate used for the glass nozzle study was slightly higher than that used for brass nozzle study. Figure 2-13 shows that bubble formation and detachment process in the standard glass nozzle subjected to the liquid cross-flow which is considered as a reference. The image sequence shows one complete cycle of bubble formation and detachment. As the images show, the bubble continues to grow from the nozzle with time. Initially, the bubble is spherical in shape however, under the influence of drag force exerted by the cross-flowing liquid, the bubble elongates in the liquid flow direction as it grows. The bubble is still attached to the nozzle due to the surface tension force but the buoyancy force tends to pull the bubble in the upward direction. As the bubble grows, the buoyancy and drag forces become dominant and their pulling effect results in the formation of a “neck” at the nozzle rim (see Figure 2-13 (q)). This pulling effect reduces the width of the neck, which in turn reduces the air supply to the bubble. Eventually, the pull due to buoyancy and drag forces cuts the bubble neck and the bubble detaches from the nozzle.

Figure 2-14 shows the bubble formation and detachment process from the novel nozzle under identical conditions as for the standard nozzle shown in Figure 2-13. As mentioned earlier, the bubble formation and detachment process from the novel nozzle comprised of these stages; expansion, collapse and pinch off. In the following, the bubble formation and detachment process over one complete cycle is described based on these three stages. Figure 2-14 shows that after the previous bubble detachment, the gas moves upward until it reaches the side-holes. Since the gas reaches the side-holes before the main nozzle hole, it starts to expand through both side-holes (see Figure 2-14(e-h)). In the present orientation, the side-holes are in-line with the liquid cross-flow. Hence, the bubble growing from the windward side-hole is directly exposed to the liquid drag, whereas, the bubble growing from the leeward side-hole lies in the low-pressure wake of the nozzle and also partially exposed to the liquid drag. The windward bubble grows at a slower rate compared to the leeward bubble. During its growth, the windward bubble expands against the liquid drag force (comprised of both friction and pressure drag) and hence this work is stored at the gas-liquid interface in the form of potential energy. After reaching a certain size, the windward bubble cannot overcome the liquid drag, which then compresses the windward bubble, which is referred to as the collapse stage. During the collapse stage, the stored potential energy in the gas-liquid interface is released and converted into kinetic energy. This kinetic energy acts on the gas volume in form of the rebound force. This rebound force along with the liquid drag force assists the compression of the windward bubble during collapse stage. The compression of the windward bubble increases the internal pressure and hence the air mass in the windward bubble rapidly moves to the leeward bubble. This increases the growth rate of the leeward bubble. During the collapse stage as the air mass from the windward bubble transfers to the leeward bubble, the liquid push back continues and the liquid enters the nozzle from the windward side-hole (see Figure 2-14(n) and (p)). As the leeward bubble grows, the buoyancy effects become significant. The combined effect of buoyancy, liquid drag from the windward side-hole and the hydrostatic pressure from the nozzle top hole form the neck of the bubble, which cuts off shortly after due to the increased effect of these forces (see Figure 2-14(q)). This stage is the pinch off stage. Note that during the neck formation and pinch off stages, the bubble is still attached to the upper section of the

leeward side-hole likely due to the surface tension (see Figure 2-14(p-r)). After pinch off, the bubble tends to rise and move downstream under the influence of buoyancy and liquid drag but due to its attachment at the upper section of the nozzle, it undergoes a slight rotation about the attachment point and then completely detaches from the nozzle.

Figures 2-13 and 2-14 also show the time from the previous detachment in each image, which provides a better idea of the associated timescales. Figure 2-13 shows that the time between two bubble detachments is about 20.9 ms, whereas, for the novel nozzle in Figure 2-14, the time reduces to 15.2 ms under the same operating conditions. Figure 2-14 also allows quantifying the timescales of different stages of bubble formation process in the novel nozzle described earlier. As figure shows, the expansion stage takes about 4 ms ( $t = 3.2$  ms to 7.2 ms, see Figures 2-14(e-j)). The collapse stage takes about 3.2 ms ( $t = 7.2$  ms to 10.4 ms, see Figures 2-14(j-n)). The pinch off stage takes about 2.2 ms ( $t = 10.4$  ms to 12.8 ms, see Figures 2-14 (n-r)). The time fraction of each stage relative to the total time period between two detachments is about 26%, 21% and 14%, for the expansion, collapse and pinch off stages, respectively.

**Figure 2-14: Sequence of bubble formation from the novel nozzle at a gas flow rate of  $826 \text{ cm}^3/\text{s}$  and liquid flow rate of  $395 \text{ cm}^3/\text{s}$ ,  $\Delta t=0.8 \text{ ms}$ .**

The image sequence in Figure 2-14 has shown the complete cycle of bubble formation and detachment from the novel nozzle. The results showed that the liquid drag force has a significant influence on the bubble expansion, collapse and pinch off. The impact of the change in liquid flow rate on these stages is shown qualitatively in Figure 2-15. The figure shows the end of each stage at three liquid flow rates. As observed, with an increase in the liquid flow rate, the timescale of the expansion process decreases and the size of the windward bubble reduces (see Figure 2-15(a)). This is likely due to the reason that an increase in the liquid drag due to the increase in the flow rate resists the expansion of the windward bubble. As the liquid flow rate increased by a factor of 2.1, i.e. from 255 cm<sup>3</sup>/s to 535 cm<sup>3</sup>/s, the expansion time reduced by 4% but the windward bubble size reduced by 40%. For the collapse stage, the figure clearly shows the effect of liquid flow rate on the windward bubble collapse. It is observed that the liquid drag pushes the windward bubble inward (see Figure 2-15(b)). At the lowest liquid flow rate, the liquid drag is relatively low but high enough to push the bubble inward. At this stage, the liquid hydrostatic force from the top hole of the nozzle also supports this pushback. As the liquid flow rate increases, the contribution of the liquid drag from the side-hole becomes dominant, which is clearly evident in the image at the highest liquid flow rate. It shows that the liquid drag not only pushed the bubble back but also was strong enough to let the bubble expand upward against the liquid hydrostatic force. The time history shows that the time interval of the collapse stage also reduces with an increase in the liquid flow rate. It is observed that the collapse stage time interval decreased by 50% when the liquid flow rate increased from 255 cm<sup>3</sup>/s to 535 cm<sup>3</sup>/s. The pinch-off time is shown in Figure 2-15(c). As observed the time at which the bubble pinches off from the side-hole does not change with an increase in the liquid flow rate.

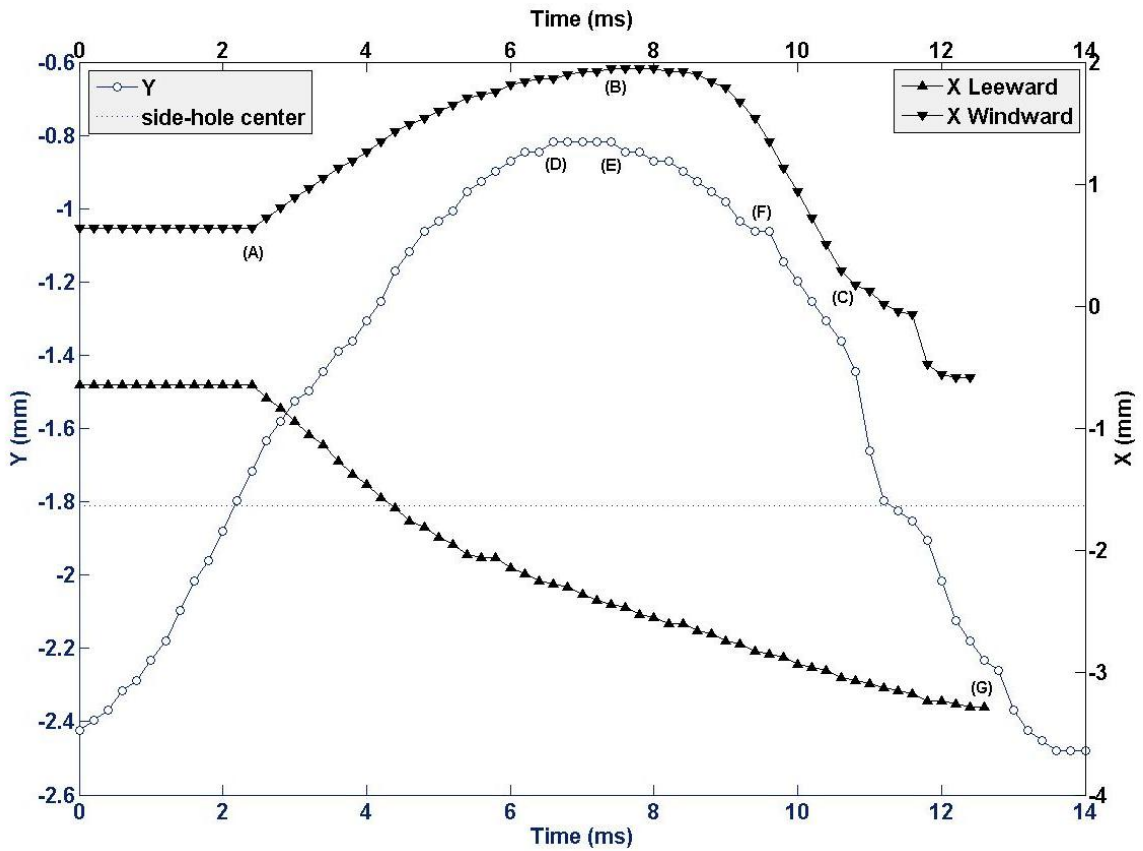

**Figure 2-15: Different stages of the bubble formation and detachment at liquid flow rates of  $255 \text{ cm}^3/\text{s}$ ,  $395 \text{ cm}^3/\text{s}$  and  $535 \text{ cm}^3/\text{s}$ .  $t=0$  is considered for the previous bubble detachment. (a) Expansion stage (b) Collapse stage (c) Pinch-off.**

Figure 2-15 shown above, depicted the impact of liquid flow rate on different stages of the bubble formation and detachment. To quantify this transient process, the bubble movement was tracked over one complete bubble formation and detachment cycle. The movement was tracked horizontally and vertically. Figure 2-16 shows the schematic of the coordinates used to track the bubble movement. As illustrated, the upper edge of the nozzle was used as the reference for the coordinate system. The edges of the bubbles (windward and leeward) relative to the mid position of the side-holes was used to quantify the horizontal extent of bubbles while the upper edge of the gas rising in the nozzle was used to quantify the vertical movement.

**Figure 2-16: Reference coordinate system.**

Figure 2-17 shows the time history of these coordinates for the novel nozzle at the lowest liquid flow rate. As observed, immediately after the previous bubble detachment the gas rises in the main nozzle until it reaches the side-holes (marked with “A” in the figure). Once it reached the side-holes, both windward and leeward bubbles start to grow. As discussed earlier, the windward bubble undergoes the expansion phase, which ends around 7.5 ms (see “B”), followed by a collapse stage which ends around 10.5 ms (see “C”). The leeward bubble continues to grow until the pinch-off at approximately 13 ms (see “G”). The vertical movement of the gas in the main nozzle is linked with the movement of the windward bubble. The gas in the main nozzle continues to rise during the early stages of the expansion phase of the windward bubble, reaches a maximum value (see “D”) and then starts to fall. The fall of the gas height becomes more rapid after the beginning of the collapse stage (see “E”). The gas level in the main nozzle continued to fall until the pinch off.

**Figure 2-17: Evolution of gas volume in X and Y direction during the bubble formation process from two side-holes at a gas flow rate of  $826 \text{ cm}^3/\text{s}$  and liquid flow rate of  $255 \text{ cm}^3/\text{s}$ .**

The time history of bubble coordinates for the novel nozzle at the highest liquid flow rate is depicted in Figure 2-18. The plot shows that the gas rises in the main nozzle for about 4 ms before reaching the side-holes (see “A”). This time is approximately 50% longer than that at the lowest liquid flow rate. The windward bubble undergoes the expansion stage, which ends around 7 ms (see “B”), which is a shorter time interval compared to that at the lowest flow rate, as discussed earlier. The collapse stage is relatively short (see “C”) and then the horizontal position remains almost constant for about 4 ms. The vertical movement of the gas in the main nozzles show a relatively different trend compared to that at the lowest flow rate. The gas level continues to rise until the end of

the collapse stage (see “D”) and stays almost constant for about 2 ms. Note that the continues rise of the gas level during the collapse stage is due to the strong pushback by the liquid drag which causes the gas to expand vertically up against the hydrostatic force as discussed earlier. The vertical level of the gas then drops sharply from “F” and continues until almost the pinch-off (“G”). The leeward bubble shows a similar trend i.e. the continuous growth until the pinch-off at about 13 ms.

**Figure 2-18: Evolution of gas volume in X and Y direction during the bubble formation process from two side-holes at a gas flow rate of 826 cm<sup>3</sup>/s and liquid flow rate of 535 cm<sup>3</sup>/s.**

### 2.3.3 Four side-holes configuration

In the preceding section, the influence of two side-holes in a standard nozzle, on the bubble formation and detachment was investigated in detail. The results show that a nozzle with two side-holes produces more bubble with small size compared to the standard nozzle particularly at low GLRs. In this section, the influence of four side-holes nozzle is investigated. Two different configurations were considered. In the first configuration, hereinafter referred to as Configuration B, four side holes  $90^\circ$  apart were created in a brass tube. The distance of these holes from the nozzle rim was constant and same as that considered for two side-holes nozzle (1.6 mm) (see Figure 2-19(a)). In the second configuration, hereinafter referred to as Configuration C, two opposite side-holes were at a distance of 0.8 mm from the rim and the other two holes were at a distance of 2.1 mm from the rim (see Figure 2-19(b)). For Configuration B, two different side-hole diameters were considered which were 0.5 mm and 0.82 mm. For Configuration C, the side-hole diameter was set at 0.5 mm. Furthermore, for Configuration C, two orientations of the nozzle were considered. In the first orientation (I), the upper side-holes (0.8 mm from the nozzle rim) were aligned with the liquid flow direction and in the second orientation (II), the nozzle was rotated by  $90^\circ$ , thus, the lower side-holes (2.1 mm from the nozzle rim) were aligned with the liquid flow direction. All nozzles were made from brass tube with the inner diameter of 0.82 mm and outer diameter of 1.62 mm (same as those used earlier for two side-holes and standard configurations). The procedure, instrumentation and operating conditions in this set of experiments were same as those for the two side-holes nozzle.

**Figure 2-19: Four side-holes nozzle configurations used in the study. (a) Regular four side-holes, Configuration B. (b) Four side-holes with different distance between holes, Configuration C.  $h_s=1.6\text{mm}$ ,  $h_u=0.8\text{ mm}$ ,  $h_s=2.1\text{mm}$ .**

Figures 2-20 and 2-21 show the influence of the four side-holes nozzle design and its orientation on the bubble detachment frequency and the bubble size as a function of liquid velocity at a given gas velocity, respectively. The results from the standard nozzle are also plotted for comparison. Similar to the two side-holes nozzle, the results illustrate that the four side-holes nozzle significantly improves the bubble detachment frequency and decreases bubble size. As mentioned earlier, for the standard nozzle with an increase in liquid velocity, the bubble detachment frequency increases. Whereas, for the four side-holes nozzle, the liquid velocity has a weak effect on both the bubble detachment frequency and the bubble size. As shown in figures, at the lowest liquid velocity, four side-holes nozzles have the bubble detachment frequency 2 times higher and the bubble size about 30% smaller than that of the standard nozzle at low liquid velocities. This effect reduces with an increase in the liquid velocity, however, at the maximum liquid velocity, the four side-holes nozzle still shows relatively higher bubble detachment frequency and smaller bubble size compared to the standard nozzle. Similar to the two

side-holes nozzle, the results show that the side-hole diameter has an influence on the bubble detachment frequency. It is observed that with an increase in the size of the side-hole, the bubble detachment frequency increases and the bubble size decreases.

The influence of the gas flow rate on the bubble detachment frequency and bubble size in four side-holes nozzles at a given liquid velocity was also investigated. The results (not shown here) indicate a trend similar to that observed for the two side-holes nozzles. That is, the bubble detachment frequency and bubble size increased with an increase in the gas velocity but at any given gas velocity, the bubble detachment frequency was greater and bubble size was smaller than that for the standard nozzle.

**Figure 2-20: Bubble detachment frequency ( $f_B$ ) versus average liquid velocity ( $V_L$ ) at a gas flow rate of  $0.168 \text{ cm}^3/\text{s}$ . Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

**Figure 2-21: Bubble diameter ( $D_B$ ) versus average liquid velocity ( $V_L$ ) at a gas flow rate of  $0.168 \text{ (cm}^3/\text{s)}$ . Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

Figure 2-22 compares the bubble detachment frequency from two side-holes and four side-holes nozzles for all common cases in a non-dimensional form. The overall trend is the same as expected i.e. the Strouhal number increased with GLR. The results also did not show a distinct difference in the bubble detachment frequency from the four side-holes and two side-holes nozzles for the given range of GLR as well as the side-hole diameter. The normalized bubble diameter for the same cases is presented in Figure 2-23. Again, the results did not indicate any clear difference among the nozzles. These results indicate that for the given range of GLR and the nozzle dimensions, the performance of two side-holes and four side-holes nozzles is very similar. There are several parameters involved in the process which include the main nozzle and side-hole diameters, distance of the side-hole from the nozzle rim, side-holes orientation relative to the liquid flow,

GLR, contact angle, etc. Variation in one or more of these parameters may distinguish the performances of two and four side-holes nozzles. Such investigation is beyond the scope of the present work. Nevertheless, the results presented in this study clearly demonstrate that the presence of side-holes in the nozzle significantly improves its performance compared to the standard nozzle, particularly at low GLRs.

**Figure 2-22: Strouhal number ( $St$ ) versus GLR. Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

**Figure 2-23: Mean bubble diameter to inner nozzle diameter ratio ( $D_B/D_N$ ) versus GLR. Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

## 2.4 Conclusion

An experimental study was conducted to investigate the bubble formation from a novel nozzle design in a liquid cross-flow over a range of gas-to-liquid flow rate ratios that varied from 0.00031 to 0.00204. Different configurations (number, size and location of side holes) and orientations of the novel nozzle design were considered. High speed imaging with back-lit shadowgraphy was used to image the bubble formation process. An in-house algorithm was used to detect bubbles and compute various characteristics. The results show that smaller bubbles at higher detachment frequency are generated from the

novel nozzle for all configurations and orientations considered, compared to the standard nozzle over the given range of GLRs. The results also showed that unlike the standard nozzle in which both the bubble diameter and the detachment frequency are heavily dependent on the liquid velocity, for the novel nozzle, both of these parameters were almost independent of the liquid velocity. It is observed that the detachment frequency increased with an increase in the gas velocity for all nozzle configurations and orientations. It is found that in comparison with the standard nozzle, the two and four side-holes nozzles generated bubbles 30% smaller in size at a detachment frequency 2-3 times higher than that of the standard nozzle at low liquid velocities. The results also indicated that for a given range of GLRs and the nozzle configurations and orientations, the performance of two side-holes and four side-holes nozzles is very similar. The in-depth investigation of the bubble formation process in the novel nozzle subjected to liquid cross-flow was conducted in a glass nozzle for better visual access. It is observed that the rebound of the bubble from a size hole under the influence of liquid drag force and hydrostatic pressure plays a key role in the early bubble detachment. It is concluded that the novel nozzle design in the liquid cross-flow exhibits significantly better performance compared to the standard nozzle especially at low GLRs.

## Chapter 3

### 3 Investigation of two-phase flow in an effervescent atomizer

#### 3.1 Introduction

Several industrial processes require dispersion of liquid into small droplets and/or spray in a gaseous atmosphere. The spray applications have a wide range depending on the desired velocity and droplet size distribution, which in turn is related to a specific range of gas and liquid flow rates and a particular application. These applications include combustion [1], chemical industry [2, 3], spray painting [4] and various pharmaceutical, agricultural and spray drying. Several spray devices have been developed as atomizers. One atomization techniques based on the aerated-liquid atomization is called “effervescent atomization”, which is used in a number of applications such as gas turbines [5, 6], internal combustion engines [7], furnaces and burners [8], and pharmaceutical sprays [9, 10].

Effervescent atomizer is a twin-fluid atomizer in which gas is injected into a liquid stream resulting in a two-phase bubble-liquid flow inside the atomizer. As this two-phase mixture exits through the orifice, the bubbles expand due to the pressure drop and the co-exiting liquid forms ligaments. These ligaments, due to the further bubble expansion along with the liquid velocity, break into small droplets [1]. The nature of the internal two-phase flow plays an important role in the atomization process and hence, the performance of an effervescent atomizer could be optimized by controlling the characteristics of the internal two-phase flow. The main components of an effervescent atomizer are gas and liquid inlets, a mixing chamber and an exit orifice. The bubble formation mode in the aeration zone of the atomizer is heavily dependent on the gas-to-liquid flow rates ratio (GLR). At low GLR, the formation mode is bubbly, which changes to jetting with an increase in the GLR, In the bubbly mode, each bubble has enough time

to become mature and detach from the injection hole while, in the jetting mode a gas jet is ejected into the liquid stream, which may breakup into bubbles further downstream [8, 11].

The internal gas-liquid flow in the mixing chamber of an atomizer has been classified into three main categories; bubbly flow, slug flow and annular flow [12-15]. At low GLR, the bubbly flow is present, which changes to the slug flow and then to the annular flow as the GLR continues to increase. In the bubbly flow, the liquid is the continuous phase whereas the gas forms the discrete phase, i.e. bubbles are dispersed and surrounded by liquid. With an increase in the GLR, the bubbly flow transforms into slug flow in which the size of bubble reaches the mixing chamber inner diameter. With a further increase in GLR, the internal flow changes to the annular flow in which gas flows in the center of mixing chamber surrounded by an annular film of liquid on the mixing chamber wall. The slug flow, due to the presence of larger bubbles approaching the exit orifice, causes significant spray pulsation and unsteadiness [16, 17]. The annular flow produces the smallest size of spray droplets compared to the other internal flow regimes [15]. However, its drawback is the requirement of the large volume of pressurized gas [13, 18] and also an unstable internal two-phase flow [15, 19].

As mentioned earlier, the behavior of the two-phase flow inside the atomizer influences the spray characteristics. Thus, the understanding of the flow regime inside the atomizer is crucial to improve the spray quality. The spray characteristics are dependent on the physical properties of gas and liquid [20, 21], operating conditions or GLR [15, 20, 22-24] shape, location and size of the aerator holes [8] and atomizer internal geometry [15, 20, 25]. A detailed review of the effervescent atomizer performance has been presented by Sovani et al. [26] for a wide range of operating conditions, liquid properties and atomizer design. Several studies have reported a decrease in the mean droplet size with an increase in the GLR [15, 20, 23, 24, 27-32].

The inherent unsteady nature of the effervescent atomization process, which is an undesirable feature, needs to be minimized. It has been reported that this unsteadiness is strongly linked to the atomizer's internal two-phase flow [20]. Luong [31] and Jedelsky

et al. [33, 34] studied the influence of operating conditions on the spray unsteadiness and observed higher spray unsteadiness when the nozzle operated in the slug flow regime, and lower spray unsteadiness when the internal two-phase flow is either bubbly or annular. Gadgil et al. [35] observed the occurrence of single- and two-phase flows intermittently inside the orifice at low airflow rates. They also concluded that these intermittent flow structures have a strong influence on the spray unsteadiness.

Huang et al. [15] experimentally investigated the influences of gas and liquid flow rates on the internal two-phase flow and spray droplet size in an outside-in effervescent atomizer. They used high-speed imaging technique to characterize the two-phase internal flow and LDV/PDA system to characterize the spray droplets. They found that an increase in the water flow rate and/or decrease in the operating pressure (lower gas flow rate), increases the droplet mean diameter and decreases the mean droplet velocity. Jedelsky et al. [36] found that the droplet size and velocity of the spray are dependent on the fluid injection pressure and GLR. They also observed that an increase in the pressure and/or GLR, decreases the droplet Sauter Mean Diameter (SMD). They also found that at the edge of spray, the droplets have higher SMD and lower velocity. They also reported that the droplet velocity distribution has a symmetric log-normal distribution at the center of the spray. Gomez et al. [37] conducted an experimental study using a horizontal gas-liquid spray nozzle. They observed that with an increase in the GLR, the droplet velocity increases and the unimodal droplet velocity distribution become more flat. Whereas, an increase in the liquid flow rate results in a narrow velocity distribution.

Jedelsky et al. [20] experimentally studied the impact of various internal geometric parameters and operating conditions on the spray droplet size in an outside-in effervescent atomizer. They performed the spray measurement using PDPA at the axial distance of 150 mm from the exit orifice which is a distance recommended in the previous studies [28, 38], as the spray becomes fully developed at 150 mm. They observed that in a mixing chamber with a single row of aeration holes, an increase in the relative length ratio of the mixing zone (the distance between the last row of the aeration holes and the exit orifice to the inner diameter of the mixing chamber) from 2.5 to 4.6, results in the smaller droplet size. This dependency decreases with an increase in the

number of aeration hole rows, and for the case of five rows of aeration holes, they did not observe any distinct trend. They argued that since larger number of aeration holes provides almost well mixed two-phase flow inside the mixing zone, longer mixing zone may not have considerable effect on the development of the two-phase flow. Their results also indicated higher spray unsteadiness in the longer mixing zone. They also observed that the best atomization occurred for five rows of aeration holes with a 3.5 relative length ratio of the mixing zone.

Jedelsky et al. [39] investigated the effect of mixing zone length on the spray droplet velocity at different radial distances from the center of the spray. They considered four different lengths of the mixing zone and observed that along the radial length (except at the spray centre), shortest mixing zone has overall largest spray velocity magnitudes (relative length ratio of 2.4). For the two middle mixing zone lengths (relative length ratios of 3.8 and 5.9), the radial distribution of the spray velocity magnitudes was almost identical. The longest mixing zone (relative length ratio of 7.4) has almost the same velocity distribution as the two middle cases except at the spray center. At the spray center, the three shorter mixing zones have the same spray velocity magnitude and the longest mixing zone has smaller spray velocity.

Mostafa et al. [29] experimentally investigated the effect of internal geometries and GLR of the effervescent atomizer on the spray droplet size. They conducted experiments using an inside-out effervescent atomizer. They found that the droplets size increased with the radial distance from the spray center and that trend increased with a decrease in the mixing zone length. They also observed that away from the spray center, the droplet size decreased with an increase in the mixing zone length. However, near and at the spray center, the droplets size is almost the same for different mixing zone lengths but showed the opposite trend i.e. a slight increase in the droplets size with an increase in the mixing zone length.

Liu et al. [40, 41] experimentally studied the effect of different internal geometric parameters of an outside-in effervescent atomizer as well as the influence of operating conditions on the spray unsteadiness and droplet size and velocity. Liu et al. [40]

observed that at low GLR, the effect of mixing zone length on the spray unsteadiness is negligible while at higher GLR, longer mixing zone length shows relatively lower spray unsteadiness, which is not in agreement with Jedelsky et al. [25 , 42]. They argued that this disagreement could be due to the differences in the operating conditions and the system design. They also investigated the effect of two different lengths of the mixing zone at a GLR of 0.1 and found that shorter mixing zone results in the smaller spray droplet with higher velocity but observed higher spray unsteadiness at the center of the spray. Liu et al. [41] conducted experiments at a GLR of 0.15 and also found that the mixing zone length has almost negligible effect on the overall radial distribution of the droplet size and velocity. While, in the central region of the spray, they observed that the longer mixing zone length provides larger size of droplets with lower velocity. However, Mostafa et al. [29] and Jedelsky et al. [39] show the strong dependency of the radial distribution of the droplet size and velocity on the mixing zone length and Sher et al. [43] argued that the optimum length of mixing zone for the atomization relies on the GLR.

The previous studies showed that gas and liquid flow rates, fluid pressure and the atomizer design strongly influence the internal flow behavior and the spray characteristics. The atomizer internal flow behavior has also been found to influence the spray characteristics. There are relatively few studies that investigated the internal flow behavior and its impact on the spray characteristics. The focus of the present research is to conduct a detailed investigation of the two-phase flow in different zones of an inside-out effervescent atomizer which has a flexible internal geometry. The high speed imaging technique allowed us to investigate the two-phase flow inside the aeration and mixing zones. This contributed to a better understanding of the process of bubble formation, their movement and/or coalescence in the aeration zone, which is not well-reported in the literature. Also there is a scarcity of detailed investigation of the internal annular flow unsteadiness inside both aeration and mixing zones. In the present study, a detailed investigation of the influence of different geometric and operating parameters on the internal and external flow behavior in an effervescent atomizer has been conducted.

## 3.2 Experimental setup and techniques

### 3.2.1 Effervescent atomizer

An effervescent atomizer has been designed and fabricated. It has full optical access, which enabled direct visualization of the two-phase flow inside the atomizer. Figure 3-1 shows the schematic of the atomizer, which is comprised of gas and liquid inlets, atomizer body, an aerator tube, and an exit orifice. The atomizer body was made of 3 mm thick acrylic tube with the inner diameter of 9.6 mm. An aerator tube was inserted inside the atomizer body, which allowed the gas to exit from the aerator holes and generate bubbles in the annular region where the liquid was flowing (i.e. an inside-out effervescent configuration). The annular region was 1.6 mm thick. The bubbles generated through the aerator holes, travel downstream with the liquid cross-flow into the mixing zone. This bubble-liquid mixture then passed through a 90° convergent section and exited through the bottom orifice to produce spray. The diameter and length of the bottom orifice were 1.27 mm and 6.35 mm, respectively (see Appendix A for the detailed drawings of the atomizer).

Since the atomizer body has circular cross-section, any attempt to directly image the flow would result in significant image distortion. To offset the atomizer body's curvature effect, it was placed inside a 1.5 mm thick square acrylic tube 25.4 mm × 25.4 mm in cross-section. The space between the atomizer tube and the square channel was filled with water to compensate for the image distortion. The lower portion of the mixing zone and the convergent section was machined directly into an acrylic block with square cross-section. The designed effervescent atomizer has the flexibility to replace the aerator tube as well as vary its position inside the atomizer body, which in turn allows changing the length of the mixing zone.

**Figure 3-1: Schematic of the effervescent atomizer used in the study (not to scale).**

### 3.2.2 Aerator tubes

In the present study, four different aerator tube configurations were considered to investigate the effect of vertical distance between aeration holes as well as the end-shape of the tube. In the first case, the aerator tube has two columns of aerator holes (9 in each column), 180 degrees apart. Two sets of aerator tubes of this configuration were built; one with the distance of 4 mm between the holes (hereinafter referred to as AR-4) and in

the other with the distance of 8 mm between the holes (hereinafter referred to as AR-8), see Figures 3-2 (a) and (b), respectively. For the second case that was focused on investigating the effect of end-shape of the tube, two aerator tubes were built; one with the flat base (see Figure 3-2(c)) and other with a conical base (see Figure 3-2(d)). Both of these aerator tubes have four columns of aerator holes, 90 degrees apart. The holes were offset by 4 mm in adjacent columns. All four configurations of the aerator tubes were made from brass tube with inner diameter of 5.3 mm, the outer diameter of 6.3 mm and the holes diameter of 0.52 mm.

**Figure 3-2: Schematic of the aerator tubes configurations used in the study, (a) with 4 mm distance between holes (b) 8 mm distance between holes. Aerator tube of identical hole configuration with (c) conical base and (d) flat base.**

### 3.2.3 Experimental setup

The schematic of the experimental setup used in this study along with its photograph are shown in Figure 3-3. The atomizer was mounted on a stand made from steel bars. Water and air were used as liquid and gas phases, respectively. A rotameter (FL-4205, Omega Engineering) which was installed upstream of the inlet valve of the atomizer was used to control and measure the water flow rate. Compressed air from the main supply line was used as the supply air. To avoid pressure fluctuations and maintain a uniform air pressure at the atomizer inlet, the air from the main supply line first passed through a settling chamber to dampen any line pressure fluctuations, and then through a narrow tube to the atomizer. The air flow rate was controlled and measured by a rotameter (FL-1448-G, Omega Engineering) installed upstream of the atomizer (see Figure 3-3). The uncertainties in liquid and gas flow rates based on the rotameters used were  $\pm 0.03$  and  $\pm 0.035$  lpm, respectively. Pressure gauges were mounted downstream of the respective rotameters to monitor the inlet pressures of water and air.

### 3.2.4 Visualization and measurement technique

#### 3.2.4.1 Internal flow

The optical access into the atomizer allowed the visualization of internal two-phase flow. A high speed imaging system was used to capture the images of flow regime inside the atomizer. It comprised of high-speed cameras (Photron SA5) with 60 mm lenses. The imaging system was connected to a PC and controlled via Photron FASTCAM Viewer software. To improve the image quality, back-lit shadowgraphy technique was used, which was comprised of a 500W halogen lamp and a diffusion screen which was placed behind the atomizer (see Figure 3-3). For the experiments focused on the distance between the aerator holes (AR-4 and AR-8), the liquid flow rate ranged from 0.757 to 1.135 lpm and the gas flow rate ranged from 0.6 to 3.5 lpm. The gas-to-liquid flow rates ratio (GLR) ranged from 0.53 to 5.84. Whereas for the rest of the configurations, the liquid flow rate ranged from 0.757 to 1.135 lpm and the gas flow rate ranged from 0.6 to 4.82 lpm (GLR ranged from 0.53 to 9.55). For all configurations, 14000 images were

captured at a rate of 20,000 frames per second at each GLR. At this frame rate, the resolution of the camera was  $704 \times 520$ .

For the set of experiments focused on the investigation of bubble formation at the aerator tube, two high speed cameras were used that were placed 90 degrees apart to capture the three-dimensional extent of the bubbles (see Figure 3-3(b)). Both cameras were synchronized to ensure simultaneous recording of the bubble movement. For the rest of experiments, one camera was used (see Figure 3-3(c)). An In-house algorithm was developed in the Matlab environment to measure the size of each bubble and compute bubble size distribution. The uncertainty of detecting the bubble boundaries was within  $\pm 1$  pixels which correspond to the uncertainty of  $\pm 0.09$  mm.

#### 3.2.4.2 External flow (Spray)

To capture the images of the spray droplets, the same imaging system was used. However, a 12X zoom lens was used instead of the 60 mm lens. The field of view for the droplet measurements was set to  $143 \text{ pixel} \times 255 \text{ pixel}$  corresponding to  $3.1 \text{ mm} \times 5.6 \text{ mm}$ . The camera frame rate was set at 150,000 frames per second. Due to a smaller field of view and higher frame rate, a continuous Diode-Pumped Solid-State laser (LRS-0532, Laser Glow Technologies) was used as a light source for back-lit shadowgraphy. The laser output was connected to a conical lens via a fibre optic cable, which produced a light cone. The measurements were made at an axial location of 150 mm downstream from the exit orifice, where the spray was fully developed [20]. At each GLR, to break any interference effects in the spray and randomize the spray pattern, 10 sets of measurements were made at different times. In each set, 5000 spray images were captured. An in-house algorithm in the Matlab environment was used for droplet detection and quantification. The code automatically detects and tracks spray droplets and computes various droplet characteristics such as the droplet cross-sectional area, perimeter and corresponding equivalent diameter, and velocity. The uncertainty of detecting the droplets was within  $\pm 2$  pixels which correspond to the uncertainty of  $\pm 0.04$  mm.

## 3.3 Results and Discussion

### 3.3.1 Internal flow

In this section, the impact of aerator tube configurations and mixing zone length, on the two-phase flow behavior inside the effervescent atomizer at different GLRs are presented and discussed.

#### 3.3.1.1 Aeration zone

The aeration zone comprised of the annular region from the most upstream aeration hole to the end of the aerator tube. As mentioned earlier, two cameras were used to image the bubble movement from the aeration holes. These cameras were positioned in a way that one camera was capturing the bubble images from a side view while the other camera was capturing the images of the same bubbles from the plan view. Figure 3-4 (a) shows an image sequence of bubble formation from the aeration holes and their advection in the annular region of the atomizer from a side view at the lowest GLR of 0.53. The process corresponds to the bubble formation in a liquid cross-flow. The image sequence corresponds to a complete cycle from one bubble detachment to the next from the most upstream aeration hole. The plan view of the same image sequence acquired from the second camera is shown in Figure 3-4 (b).

The downward movement of the bubbles is influenced by several force components which are (i) liquid pressure drag force from the top, (ii) liquid skin friction drag from the sides, (iii) skin friction drag due to the aerator exterior surface and the atomizer body inner surface, and (iv) buoyancy force. Any changes in these force components affect the local advection velocity of the bubbles. The bubbles formed from the most upstream aeration hole are generally distinct. They typically start to move with a relatively constant velocity. However, as they advect downward, another bubble is formed from the same aeration hole upstream. The low-pressure wake formed by the earlier (downstream) bubble, increases the velocity of the new (upstream) bubble. Furthermore, when the bubble passes over a downstream aeration hole, it may interact and coalesce with the bubble forming from that hole or the gas may be injected directly into that bubble. In either

case, the bubble size grows. It should be noted that the vertical extent of the bubbles was limited due to the fixed thickness of the annular region of the aeration zone and hence the only growth option was in the lateral as well as streamwise directions. The images in Figure 3-4(b) confirm that the bubble size continued to increase in the lateral-streamwise plane in the downstream direction. As the bubble grows in the lateral-streamwise plane, the magnitudes of all force components increase, which cause a reduction in the advection velocity of the bubble (likely due to the relatively larger increase in the buoyancy and surface friction drag). These processes continue as the chain of bubbles advects downward, and as a result, the distance between the bubbles continues to decrease and eventually, the bubbles start to interact with each other and cause further bubble coalescence. The interaction and coalescence of the bubbles is evident in Figure 3-4. The images also show some meandering of the bubble chain, which is likely due to the change in the liquid flow conditions due to bubble growth. At the end of the aerator tube, these bubbles enter the mixing zone.

**Figure 3-4: Image sequences showing the bubble formation from AR-4 at a GLR of 0.53 ( $\Delta t=0.45$  ms). (a) Side view (b) Plan view.**

The effect of the distance between aeration holes is shown in Figure 3-5 at three different GLRs. The results illustrate that at a given GLR, larger bubbles are present when the distance between the aeration holes was large. This could be due to the reason that the length of the aeration zone at the end of the aerator tube is larger for the AR-8 case (72 mm) compared to that for the AR-4 case (40 mm). Therefore, the hydrostatic pressure upstream of the aeration zone is higher for the AR-4 and hence, the liquid drag force on the bubble formed at the upstream holes in AR-4 would be higher than that for the AR-8. This would result in higher net downward force that would cause higher bubble advection velocity. This was further confirmed by a detailed visual inspection of the image sequences that show relatively higher bubble advection velocities for AR-4. The higher advection velocity and shorter distance of the aeration zone do not allow much time for bubbles to grow and undergo multiple coalescence before exiting the aeration zone. This phenomenon is clearly visible in the images at the low GLR. An increase in GLR (i.e. an increase in the gas flow rate and/or a decrease in the liquid flow rate) increases the bubble size and the chances of bubble coalescence further increases regardless of the holes' distance. Thus, the effect of the aeration-hole distance on the bubble coalescence decreases, which is evident in the images at the high GLR.

**Figure 3-5: Effect of distance between holes at three different GLRs, (a) Side view (b) Plan view. The dashed line indicates the location of the aeration holes.**

### 3.3.1.2 Transition from aeration zone to the mixing zone

The image sequences in Figure 3-6 illustrate the transition of bubbles from the aeration zone to the mixing zone over a range of GLRs. Figure 3-6(a) shows the process at the lowest GLR of 0.53. As discussed earlier, at low GLR, smaller bubbles are generated in the aeration zone which then enter the mixing zone. As mentioned in the Experimental setup section, the standard aerator tube has a flat base, which causes a flow separation leading to the formation of a large separation bubble in the wake region. As the figure shows, the bubbles generated in the aeration zone are relatively small and hence when they enter the mixing zone, they interact with the separation bubble. Such interaction could take various forms, which are (i) causing the separation bubble to meander, (ii) coalescence of smaller bubbles with the separation bubble, (iii) collision of the smaller bubbles with the separation bubble without coalescence (iv) coalescence of smaller bubbles and the interaction of coalesced bubble with the separation bubble, and (v) deformation and breakup of the separation bubble. These forms are clearly evident in Figure 3-6(a).

As the GLR increased, relatively larger bubbles are formed in the aeration zone. These bubbles interacted with the separation bubble as they entered the mixing zone. Similar interactions as mentioned above are also observed but the extent is different since the gas flow is relatively large compared to that of the liquid flow. With a further increase in GLR, the bubble size further increased and stronger interaction with the separation bubble is observed which caused its breakdown. At the highest GLR, the flow is almost annular and hence a continuous gas core is established in the middle of the mixing zone. The results in Figure 3-6(d) also indicate the unsteadiness of the annular flow in the mixing zone. This could be due to the reason that in the annular flow, gas core occupies the major portion of the cross-sectional area of the mixing zone that leads to a reduction in the liquid velocity and an increase in the upstream liquid pressure. The reduction in the liquid velocity influences the bubble formation mode in the aeration zone i.e. the slug bubble formation that creates unsteadiness in the mixing zone. The upstream pressure buildup after certain magnitude pushes the liquid flow down that changes the bubble formation from slug to smaller bubbles that restores the smooth annular flow. Huang et

al. [15] also reported unsteadiness in the annular flow regime in an effervescent atomizer. Otahal et al. [19] also reported similar behavior and classified them as either (i) classical annular flow with middle air core and smooth interface or (ii) churn flow with wavy interface. The analysis of the data showed that this unsteadiness occurs frequently and causes instability in the spray.

### 3.3.1.3 Flow dynamics inside the mixing zone

The effect of GLR on the two-phase flow inside the mixing zone for the standard aerator tube is shown in Figure 3-7. The results show that an increase in the GLR changes the flow regime inside the mixing zone. At low GLR, the regime is bubbly flow, which then changes to the slug flow and then to the annular flow as GLR continues to increase due to an increase in the gas flow rate or decrease in liquid flow rate. The bubbly flow was observed at GLRs of 0.53, which at GLR of 3.17, transformed into the slug flow where big bubbles of almost the same size as the inner diameter of the atomizer body were present. At GLR of 9.55, the internal flow changed to the annular flow in which gas flow was observed in the center and an annular liquid flow on the mixing chamber wall.

The above results provide a qualitative comparison and a clear perception about the nature of the two-phase flow and the associated flow regimes in the mixing zone. For a better comparison, the results are quantified in terms of the bubble size distribution under various regimes. As mentioned earlier in the experimental setup section, an in-house code was used for this purpose. The code provided the information about the vertical extent of each bubble, which is considered as the characteristic size of the bubbles. The bubble size distributions in the mixing zone for the same conditions as in Figure 3-7(a), are presented in Figure 3-7(b) in the form of Probability Density Function (PDF). The results show that at low GLR, the bubble size is distributed in a narrow band, implying more uniformity in the bubble size. Note that the distribution tail on the right side is associated with the separation bubbles present in the mixing zone as mentioned in the previous section. Note that at the GLR of 0.53, the long annular separation bubble was neglected in the bubble size distribution since it could significantly bias the statistical results of bubble size in the mixing zone. The results also show that with an increase in the GLR, the size distribution bandwidth became wider and also the distribution peak shifted towards right. At the highest GLR, the flow was annular and hence the bubble size corresponds to the height of the annular bubbles.

Figure 3-7(c) shows the mean bubble diameter ( $D_B$ ) as a function GLR for the same cases as in Figures 3-7(a) and (b). The results show that the mean bubble diameter increased with an increase in the GLR, as expected. The increase in the bubble diameter from GLR of 0.53 to 3.17 is gradual i.e. bubbly flow regime to slug flow regime. However, with a further increase of the GLR from 3.17 to 9.55 the mean bubble diameter increased sharply due to the formation of slug and annular flow inside the mixing zone. As illustrated in Figure 3-7(c), the bubble diameter inside the mixing zone increased by 46% as the GLR increased from 0.53 to 3.17.

#### 3.3.1.4 Effect of the aerator tube end shape

As shown earlier in Figure 3-6, the standard aerator tube with the flat-base, induces a separation bubble whose size is influenced by the GLR, the size of bubbles exiting the aeration zone and the local interactions of these bubbles with the wake. This separation bubble has a direct impact on the bubble-liquid mixture in the mixing zone, which in turn affects the spray behavior. The impact of the aerator tube base shape on the bubble-liquid mixture in the mixing zone was investigated for two configurations of the aerator tube geometry. In the first configuration standard aerator tube with the flat-base (as discussed

earlier) was considered while in the second configuration, a cone was added to the bottom end of the aerator tube to eliminate the wake formation and hence the separation bubble. Figure 3-8 presents images illustrating the two-phase flow inside the mixing zone for the two aerator tube base configurations at three different GLRs. At the lowest GLR (0.53) for the standard case, the wake induced a large separation bubble immediately downstream of the bottom end of the aerator tube (see Figure 3-8(a)). This separation bubble often detaches from the tube end (as seen earlier in Figure 3-6) and advects into the mixing zone. This separation bubble as it advects into the mixing zone, normally deforms and interacts with the bubbles entering the mixing zone from the aeration zone. These interactions contribute to the non-uniformity of the bubble size as well as the flow unsteadiness in the mixing zone (see Figure 3-6). However, when the conical insert was attached to the bottom face of the aerator tube, it streamlined the flow and hence the wake formation was suppressed, thus, no separation bubble was formed. This resulted in more bubble size uniformity and flow steadiness (see Figure 3-8(a)).

As the GLR increased, for the standard aerator tube, larger bubbles are formed in the aeration zone that have stronger interaction with the separation bubble that often led to the breakdown of the separation bubble. However, with the conical-base aerator tube, no such interaction was present and the only interaction was among the bubbles entering the mixing zone from the aeration zone (see Figure 3-8(b)). The overall size of the bubbles in the mixing zone is relatively large, as expected due to the increase in the bubble size with GLR in the aeration zone. Although the number of bubbles in the mixing zone reduced, the bubble size uniformity is still better for the conical-base case. At the highest GLR, the flow typically becomes annular in the aeration zone, i.e. the gas occupies most of the flow region and the liquid flow is mainly restricted to the outer surface as thin liquid film [15]. As a result, the aerator tube end normally lies in the gas flow and hence, the effect of the tube-end shape becomes almost irrelevant to the flow regime inside the mixing zone (see Figure 3-8(c)). It should also be noted that the presence of the cone reduces the early coalescence of bubbles as they enter the mixing zone. The results in Figure 3-8 are presented for three GLRs which depict different flow regimes, and compared the two aerator configurations. The results show that for all flow regimes, the new aerator base

configuration with a conical bottom maintained smaller bubbles and bubble size uniformity.

The blunt edge at the bottom end of the standard aerator causes the formation of the separation bubble immediately downstream of the aerator tube in the mixing zone (see Figure 3-8). A detailed inspection of the image sequences also revealed that at certain GLRs, the separation bubble often stretches more than half way through the mixing zone, which is likely due to the skin friction drag induced by the liquid flow and the surface tension force. Often this big bubble detaches from the end of the tube and flows downward through the mixing chamber and significantly affects the flow uniformity in the mixing zone and leads to the spray unsteadiness. The results in Figure 3-8 show that for all flow regimes, the new aerator configuration with a conical base maintained smaller bubbles and bubble size uniformity.

**Figure 3-8: Effect of aerator tube base configuration on the flow behavior inside the atomizer at different GLRs. The length of the mixing zone is 52 mm.**

The effect of aerator tube base configuration on the bubble size distribution is shown in Figure 3-9 at two GLRs (0.53 and 3.17). At low GLR (Figure 3-9(a)), the results show that the bubble size distribution has a narrower band with the conical-base aerator compared to the standard flat base aerator. It is also observed that in the presence of the conical-base, the bubble diameter ranged from 0.5 mm to 4.5 mm while for the flat-base, the bubble diameter ranged from 1 mm to 6.5 mm (see Figure 3-9(a)). The overall mean diameter of bubbles for the conical-base is 2.3 mm which is about 20% smaller than the mean bubble diameter of 2.9 mm for the flat-base (see Figure 3-9(a)). These results indicate that the aerator tube with the conical-base generates more uniform bubbles, smaller in size compared to the standard flat-base aerator particularly in the low GLR range.

As the GLR increased (see Figure 3-9(b)), the effect of cone decreased as discussed earlier, however, the cone prevented the formation of very large bubbles in the mixing zone. These large bubbles for the flat-base are most likely associated with the stronger interaction of the separation bubble with the bubbles entering from the aeration zone that increased coalescence and more frequent breakdown of the separation bubble. The results at this GLR also show that for the conical-base case, the bubble diameter ranged from 1 mm to 6 mm while the flat-base case, the bubble diameter ranged from 1 mm to 13 mm. Figure 3-9(c) shows the mean bubble size for the conical-base aerator tube and the standard aerator tube with the flat-base. It is observed that the conical-base case generates smaller bubble size for all the GLRs. It is observed that at these GLRs, the bubble size in the presence of a conical-base aerator tube is on average, 11% smaller than that for the flat-base aerator tube.

(c) Mean bubble diameter versus GLR. Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

### 3.3.1.5 Effect of the mixing zone length

The effect of mixing zone length on the bubble-liquid flow behavior inside the mixing zone is depicted in Figure 3-10 for three mixing zone lengths (32 mm, 52 mm and 75 mm) at three different GLRs. The images show that a decrease in the length of the mixing zone resulted in smaller bubble with more uniformity inside the mixing chamber. The presence of smaller bubble is likely due to the reason that the long mixing zones increase the chances of bubbles coalescence, which form large bubbles [39]. Furthermore, due to the randomness of the coalescence occurrence, the long mixing zones also contribute to the non-uniformity in the bubble size. Hence, shorter mixing zone could generate steady

spray at GLRs higher than that for the longer mixing zones. For instance, the results show that the flow regime inside the 75 mm long mixing zone became slug flow at the medium GLR of 3.17, while at the same GLR, the flow in a 32 mm mixing zone shows almost bubbly flow (see Figure 3-10 (a) and (b)). The results show that at high GLR, flow inside the 75 mm mixing zone becomes unsteady while the lower mixing zone length still shows relatively stable behavior.

**Figure 3-10: Effect of mixing zone length on the flow behavior in the mixing zone at different GLRs. (a) GLR=0.53, (b) GLR=3.17, (c) GLR=9.55.**

The bubble size distribution for different mixing zone lengths is shown in Figure 3-11(a) and (b) at GLRs of 0.53 and 3.17, respectively. At the low GLR (Figure 3-11(a)), the results show a clear effect of mixing zone length on the bubble size distribution. It is observed that for the shortest mixing zone, the bubble size distribution is relatively narrow banded and the bandwidth increased with an increase in the mixing zone length and shifted towards the right. Bubble size ranged from 0.3-3.3 mm, 0.5-4.5 mm and 1.1-5.9 mm for 32 mm, 52 mm and 75 mm mixing zone lengths, respectively. At the higher GLR (Figure 3-11(b)), the effect of mixing zone length becomes less significant for longer mixing zones. Bubble size ranged from 1.4-5.6 mm, 1.2-6.7 mm and 1.2-9.6 mm for 32 mm, 52 mm and 75 mm mixing zone lengths, respectively. Figure 3-11(c) shows the mean bubble size for the three mixing zone lengths at different GLRs. It is observed that for the mixing zone with 32 mm length, bubble diameter has a linear relation with the GLR which becomes nonlinear at larger mixing zone lengths. The results show that at the GLRs of 0.53 and 3.17, the average bubble size in 32 mm long mixing zone is 32% smaller than that in the 75 mm mixing zone.

### 3.3.2 External flow (Spray)

In the preceding section, the effects of various parameters on the bubble-liquid two-phase flow inside the effervescent atomizer are presented and discussed. The variation in the internal two-phase flow has an impact on the spray characteristics. In this section, the effect of the change in the two-phase flow behavior due to the variation in the GLR, aerator tube configuration and mixing zone length, on the spray characteristics are presented and discussed.

(a)

(b)

(c)

**Figure 3-11: Effect of different mixing zone lengths on the bubble size (a), (b) Probability Density Function (PDF) of the bubble diameter ( $D_B$ ) at  $GLR=0.53$  and  $GLR=3.17$ , respectively. (c) Mean bubble diameter versus  $GLR$ . Error bars are smaller than the size of bullets.**

### 3.3.2.1 Effect of $GLR$

As Figure 3-7(a) shows,  $GLR$  has an impact on the bubble-liquid two-phase flow inside the atomizer. It is observed that as the  $GLR$  increases, the bubble-liquid mixture mode changes from bubbly to slug to annular. In the bubbly flow mode, the bubbles inside the mixing zone are smaller and relatively uniform in size. With an increase in  $GLR$ , the bubbles become larger and their size distribution becomes wider (see Figures 3-7 (b) and (c)). Figure 3-12 shows the spray characteristics (i.e. the droplet size and droplet velocity distributions) correspond to the internal flow cases shown in Figures 3-7(a) and (b). Figure 3-12(a) shows the mean diameter of the spray droplets. As mentioned earlier in the experimental setup section, the spray measurements were made at a distance of 150

mm from the exit orifice, where the spray was fully developed [20]. The droplet size distribution is relatively wider at the low GLR, which becomes narrower with an increase in the GLR.

The results also show that at higher GLR, the spray has more number of smaller droplets. This trend is consistent with previous studies that showed that the overall droplet size decreases with an increase in the GLR [15, 20, 24, 28-31]. As earlier results show, the internal flow at high GLR is annular which implies that in the mixing zone, the gas flow covers almost the entire cross-sectional area with the liquid flow in the form of film along the mixing zone wall. In such case, the droplet formation is almost in a continuous mode. The higher amount of gas flow allows better atomization [15]. However, the downside of operating at high GLRs under annular flow mode is that the atomizer needs significantly large flow rate of pressurized gas, which could be an issue in various applications [1, 27, 31]. Similarly, at high GLR, the liquid flow rate is relatively very low and hence the delivery of required amount of liquid droplets may be an issue. At low GLR, the flow regime inside the mixing zone is the bubbly flow. When this flow exits the orifice, the individual bubbles shatter and form the liquid droplets [1]. Any spatial gap between the two bubbles filled with liquid and hence, between the two consecutive bubble shattering, pure liquid discharges from the orifice, which results in larger droplets or liquid ligaments. If the time difference between the two bubbles shattering is large, it also causes pulsation and instability in the near-field spray [35]. Furthermore, with an increase in the GLR, the bubble coalescence increases and the slug bubbles are formed in which the difference in the size of approaching bubbles to the exit orifice also results in pulsation in the spray [16, 34]. Figure 3-12(b) shows the corresponding droplet velocity distribution. As the figure shows, the velocity distribution is unimodal, which is consistent with previous studies [36, 37]. The results show that the velocity distribution is narrow-banded at the low GLR and becomes wider with an increase in the GLR. This trend is consistent with [36]. The peak velocity magnitude does not show a specific trend over the given GLR range [37].

### 3.3.2.2 Effect of cone

The results in the preceding section show that the flat-end aerator tube causes the flow separation and forms a separation bubble, which affects the bubble dynamics in the mixing zone, particularly at low GLRs. It has also been shown that by adding a conical base to the aerator tube, the flow separation and hence the separation bubble is suppressed which resulted in more uniform bubble size distribution. Figure 3-13(a) shows the droplet size distribution for the low GLR of 0.53 with and without the cone (corresponding to the same case as for the internal flow shown in Figure 3-9(a)). The figure shows that the conical base of the aerator tube results in a slightly larger number of smaller droplets as well as slightly narrower distribution. The distributions at the higher GLRs (not shown here) indicate that the droplet size distribution with and without cone remains relatively similar however, the aerator with the flat base generated slightly larger number of smaller droplets. Figure 3-13(b) summarizes the results in the form of mean droplet diameter. It is observed that at low GLR, the conical base caused a reduction in the mean droplet size, which as discussed earlier, could be due to the suppression of the separation bubble and relatively uniform bubble distribution inside the mixing zone. At higher GLRs, the mean droplet diameter was found to be smaller for the flat-base aerator tube case. As shown earlier, with an increase in the GLR, the liquid flow rate decreases and hence the flow separation effect becomes insignificant.

Figure 3-14(a) shows the distribution of droplet velocity for the GLR of 0.53 with and without the cone. The results show that the droplet velocity distribution is relatively narrow-banded without the cone. It is also observed that velocity distribution with the cone is shifted to the right indicating that the droplet velocities are relatively higher in this case. At higher GLRs (not shown here) the droplet velocity distributions with and without cone were similar with a slight shift of velocity distribution to the right in the presence of cone. Figure 3-14(b) summarizes the results in the form of mean droplet velocity. The mean droplet velocity is normalized by  $V_{La}$ , where  $V_{La}$  is the liquid velocity in the liquid inlet of the atomizer. The results show very similar trend for the cases with and without the cone but the normalized droplet velocity magnitude is slightly higher in the presence of the conical-base aerator tube.

### 3.3.2.3 Effect of mixing zone length

The influence of mixing zone length on the internal bubble-liquid two-phase flow is presented in Figures 3-10 and 3-11. As discussed earlier, at low GLR, the bubble size is relatively small and uniform in the shorter mixing zone and an increase in the mixing zone length severely affects the mixing of the bubbly flow due to the increases in the bubble coalescence [39]. Figure 3-15(a) shows the droplet size distribution for the lowest GLR of 0.53 for the three mixing zone lengths. The results show that the number of smaller droplets is largest for the shortest mixing zone length, which decreases with an increase in the mixing zone length. The rest of the distributions are almost identical for all cases. As the GLR increases to 3.17, the two-phase flow inside the 52 mm and 75 mm length shows the slug flow and almost similar bubble size distribution (see Figures 3-10 and 3-11(a) and (b)). This effect is manifested in the droplet size distribution for that GLR in Figure 3-15(a). Figure 3-15(b) shows the mean droplet diameter for different mixing zone lengths over a range of GLRs. At the low GLR, there is a decreasing trend of droplet diameter with a decrease in the mixing zone length however, the trend changes with an increase in the GLR. At the medium GLR, the two-phase flow inside the 52 mm and 75 mm long mixing zones shows the slug flow which resulted in the larger and almost same mean bubble size (see Figure 3-11(c)). Similar effect is observed in the spray droplet size as well. At the high GLR, the mean droplet size for the 32 mm and 52 mm mixing zones were almost the same while the 75 mm mixing zone has larger mean droplet size. As mentioned earlier, at this GLR, the flow for all three mixing length cases was annular and hence, the impact of bubble size was irrelevant. The larger droplet size observed in 75 mm mixing zone length is likely due to the unsteadiness of the internal flow as discussed earlier.

(a)

(b)

**Figure 3-15: Effect of the different mixing zone length on the droplet diameter in the form of (a) Probability Density Function (PDF) at GLR=0.53 (b) Mean droplet diameter versus GLR. The aerator tube has the conical base. Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

The distribution of droplet velocity for three mixing zone length at the GLR of 0.53 is shown in Figure 3-16(a). The results show variation in the distribution however, the distribution trends are not monotonic. The droplet velocity distribution trends for the shortest and longest mixing zones are very similar with the exception that the velocity distribution for the shortest mixing zone is slightly sifted towards right i.e. slightly larger velocity. The middle mixing zone showed relatively larger droplet velocity and relatively wider distribution. Figure 3-16(b) shows the normalized droplet velocity for different mixing zone lengths at various GLRs. The results show an increase in the droplet velocity with GLR for all cases. The comparison among different cases shows very similar trends with slightly lower velocity for 75 mm long mixing zone. These results indicate that the mixing zone length does not have a distinct impact on the droplet velocity. The variations observed in the magnitudes for different mixing zone lengths could be due to experimental uncertainties or the spray unsteadiness. As mentioned in the literatures, Jedelsky et al. [39] observed that at the spray center, the three shorter mixing zones have the same spray velocity magnitude and the longest mixing zone has smaller spray velocity. Liu et al. [40] also observed that at the central region of the spray, the length of mixing zone has small effect on the droplet velocity. However, the longer mixing zone length provides lower droplets velocity.

(a)

(b)

**Figure 3-16: Effect of the different mixing zone length on the droplet velocity in the form of (a) Probability Density Function (PDF) at  $GLR=0.53$ , (b) Normalized droplet velocity ( $V_p/V_{La}$ ) versus  $GLR$ . The aerator tube has the conical base. Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

### 3.4 Conclusion

An experimental study was conducted to investigate the effect of atomizer internal geometry on the internal and external two-phase flows in an effervescent atomizer using high-speed imaging system. The bubble formation process and the impact of the distance between holes inside the aeration zone were investigated. The results illustrate that at a given GLR, larger bubbles are present when the distance between the aeration holes was large. The impact of the aerator tube configurations and mixing zone length on the two-phase flow regime, the size of bubbles inside the mixing zone and the spray droplet characteristics at different GLRs was also studied. It was observed that an increase in the GLR leads to transition the internal two-phase flow from bubbly to slug and then to annular flow. In addition, the results illustrated a reduction in the spray droplet size with an increase in GLR. The results also show that the droplet velocity distribution is narrow banded at the low GLR and becomes wider with an increase in the GLR and the normalized droplet velocity increases with an increase in the GLR.

It was observed that the end-shape of the aerator tube has an impact on the two-phase flow behavior in the atomizer. An aerator tube with the conical end-base was manufactured and tested. The results show that the separation bubble at the trailing edge is suppressed by this configuration and results in more uniform and smaller bubbles compared to the standard aerator tube with flat base. It was observed that at low GLR, the conical base caused a reduction in the mean droplet size. While, at higher GLRs, the mean droplet size was found to be smaller for the flat-base aerator tube case. This is likely due to the reason that with an increase in the GLR, the liquid flow rate decreases and hence the flow separation effect becomes negligible. So the effect of conical base is significant on the internal flow and it improves the atomization when the internal two-phase comprised of the bubbly flow. The results of the mean droplet velocity for the aerator with and without conical base show very similar trends for both cases, but the normalized droplet velocity magnitude is slightly higher in the presence of the conical-base aerator tube.

The length of the mixing zone was found to have an impact on the bubble size distribution inside the mixing zone. The results show that shorter mixing zone length generates more uniform and smaller bubbles. This is likely due to the reason that the shorter mixing zones support the suppression of the bubble coalescence. It was observed that smaller mean droplet size is produced with shorter mixing zone at low GLRs when the internal flow is in the bubbly regime. It was also illustrated that the longest mixing chamber (75 mm) results in larger droplet size compared to the other mixing zone lengths (32 mm and 52 mm). The results of the normalized droplet velocity for different mixing zone lengths show very similar trend for all cases. However, the normalized droplet velocity is slightly lower for the longest mixing zone. It is concluded that a conical-base aerator tube and a reduction in the mixing zone length results in an improvement of the spray steadiness and the atomization process.

## Chapter 4

### 4 Effect of bubble breaker on the effervescent atomization process

#### 4.1 Introduction

One type of the twin-fluid atomizers is the effervescent atomizer, which through the bubbling of gas into the liquid stream substantially improves the atomization process in terms of the finer spray [1]. The spray applications are fully dependent on the desired spray velocity and droplet size, where for each application and a specific range of operating conditions, a particular spray mechanism is suitable. To design an atomizer, the spray droplet size is a crucial parameter. To produce fine spray, the effervescent atomization technique is used in several applications such as gas turbines [2, 3], internal combustion engines [4], furnaces and burners [5], and pharmaceutical sprays [6].

The main components of an effervescent atomizer are gas and liquid inlets, a mixing chamber and an exit orifice. The injection of gas into the liquid stream through the holes in the aerator tube forms bubbles in the liquid stream [7, 8]. The gas-liquid mixture flows downstream and then exits from the orifice. Due to a high-pressure drop at the exit orifice, the gas expands suddenly and forms small droplets [8]. The internal two-phase flow plays a significant role in the performance of the atomizer in terms of spray properties [9]. Gas-liquid flow inside the effervescent atomizer and the exit orifice has been categorized into three flow regimes; bubbly flow, slug flow and annular flow [7, 10, 11]. Gas injection and bubble formation from the aerator tube as well as bubble dynamics in the mixing zone affect the bubble size as they move towards the exit orifice [12]. From the mixing zone, bubbles reach the convergent section, where the bubbly flow accelerates and the pressure reduces. A reduction in the pressure results in the bubble expansion [13-

15]. The length to diameter ratio ( $l/d$ ) of the exit orifice may cause further fragmentation of bubbles [13].

Gas and liquid flow rate or gas to liquid flow rates ratio (GLR) influence the bubble formation from the aeration holes. With an increase in the gas flow rate, bubble formation from the inlet holes changes from the bubbly mode to the jetting mode [4], while the flow inside the mixing zone changes from the bubbly flow to the annular flow [12, 16, 17]. GLR also plays an important role in the spray mean droplets size [7, 8, 16, 18-21], where the latter decreases with an increase in GLR [8, 16, 18-21]. The bubbly flow is present at low GLR, and with an increase in the GLR, the bubbly flow changes to the slug flow and then to the annular flow. In the bubbly flow, the liquid and gas are the continuous and discrete phases, respectively, i.e. bubbles are dispersed in the liquid stream. As the GLR increases, the bubbly flow transforms into the slug flow. In the slug flow regime, the size of bubble reaches the mixing chamber inner diameter. When the GLR further increases, the internal flow changes to the annular flow. In the annular flow regime, the gas flows in the center of mixing chamber surrounded by an annular film of liquid on the mixing chamber wall. The slug flow causes significant spray pulsation and unsteadiness due to the presence of larger bubbles approaching the exit orifice. The bubbly flow has been reported to produce a steady spray [16].

The annular flow inside the mixing chamber produces small-size droplets compared to the other two flow regimes [1, 16]. However, the generation of annular flow requires a high gas flow rate, which may be an issue in some applications. Since the gas phase is a crucial parameter to produce fine spray, the bubbles size inside the mixing zone and bubble distribution approaching the exit orifice have a significant effect on the spray droplet size [21].

One of the most important spray characteristics is droplet size which is dependent on the atomizer internal geometry [19, 22-25] and operating condition [16, 18-21, 24, 25]. An experimental study to evaluate the influence of operational conditions and several geometric parameters on the droplet size in the effervescent atomizer spray has been conducted by Jedelsky et al. [19]. The size and number of aerator holes, their location,

and the diameter of the mixing chamber were the parameters considered by the study. They reported that smaller aeration holes in larger numbers led to a decrease in the spray droplet size. The influence of internal gas-liquid flow on the axial mean velocity and size of the spray droplets was experimentally investigated by Huang et al. [16] who used high-speed imaging technique to characterize the two-phase internal flow and LDV/PDA system to characterize the spray droplets. They observed an increase in the droplet mean diameter and a decrease in the mean droplet velocity with an increase in the liquid flow rate. The flow regime inside the exit orifice plays an important role in the stability of the spray. Maldonado et al. [26] observed better spray stability with a bubbly flow inside the exit orifice compared to an intermittent flow of gas-liquid. Sen et al. [15] experimentally investigated the injection of gas into the liquid cross-flow inside a horizontal effervescent atomizer. They used flow visualization to study the bubble formation and breakup inside the atomizer. They found that the choking of the exit orifice by large bubbles generates a pressure pulse towards the upstream flow and concluded that the generated pressure pulse results in the breakup of the gas jet in the mixing chamber and causes fragmentation and deformation of the bubbles approaching the exit orifice.

As mentioned earlier, the bubbly flow approaching the exit orifice is crucial for atomization and spray steadiness. To produce small-size bubbles at a given GLR, an easier way is to retain the bubbly flow inside the mixing chamber by bubble fragmentation (breakup) mechanism. The bubble fragmentation or breakup is a process by which a bubble splits into two or more bubbles i.e. the disintegration of a large bubble into smaller bubbles. Surface tension always acts to maintain the bubble-liquid interface stable while the shear forces (disruptive force) acts to destroy it. Once the shear forces become large enough, the surface tension is not able to retain the bubble-liquid interface stable and the breakup occurs [27]. There are different processes that cause the bubble breakup, which include breakup in stagnant flow or turbulent flow, breakup due to the resonance, velocity gradients, shock or sound waves, electrical forces or impingement effect [28].

Jagannathan et al. [29] experimentally studied the effect of ultrasound on the bubble disintegration inside a horizontal effervescent atomizer using high-speed imaging. They

observed that the acoustic pressure difference results in the change of bubble shape from spherical to ellipsoid. The bubble then elongates and a ligament shape is formed which further breaks into smaller bubbles to maintain the surface tension. They reported the breakup of bubbles from 5-10 mm range into 2 mm or less, depending on the ultrasonic power input. They concluded that the ultrasound is an effective way to produce small bubbles.

Bubble breakers in which the bubbles are forced to divide into two or more bubbles have been used in different devices such as effervescent atomizers [11, 21, 24] and chemical bubble column reactors [30-32] to produce uniform small-size bubbles. Bubble column reactors in which bubbles are disintegrated by a perforated sheet inside the column has been investigated previously [30-32] and has been found as an effective way to break bubbles.

Ghaemi et al. [33] experimentally investigated the effect of aeration system on the flow inside and outside an effervescent atomizer. The first aeration system was an aerator tube with multi injection hole and the other was a porous media. They found that at the same GLR, the bubble size approaching the exit orifice decreases in the presence of the porous media, which results in a more steady spray with slightly smaller droplet size compared to the multi-hole injector. Gomez et al. [21] experimentally studied the impact of GLR and bubble breaker on the internal flow and spray in a horizontal effervescent atomizer using shadowgraphy. They also performed the experiments using two metal plates with different sizes of holes located upstream of the mixing chamber. They found that the bubble breaker produces finer bubbles inside the atomizer. They concluded that at a constant GLR, smaller bubble size leads to the generation of small droplets due to an increase in the void fraction. They also found that an increase in GLR decreases the droplet size. They also observed better performance of atomizer using a bubble breaker, which results in smaller droplet size at higher GLR compared to the atomization without a bubble breaker. They indicated that the size of the bubble breaker orifice affects the bubble size inside the mixing chamber. They observed that the smaller hole diameter of the bubble breaker results in smaller bubble size at higher GLR however, the bubble sizes were comparable for both size of bubble breakers at low GLR. Mostafa et al. [24]

experimentally investigated the effect of effervescent atomizer internal geometries and GLR on the spray droplet size. They conducted their experiment using an inside-out effervescent atomizer. They reported that the spray droplet size depends on the GLR, which decreases with an increase in the GLR. They also investigate the effect of a perforated insert on the droplet size and velocity, over a range of GLR from 0.1 to 0.6 and found that the perforated plate results in a reduction in the droplet size and an increase in the droplet velocity. Sutherland et al. [11] used a perforated sheet inside an effervescent atomizer at a GLR of about 0.02 and found that the perforated sheet leads to smaller droplet size.

As the above literature review shows, the performance of an Effervescent atomizer is dependent on the nature of the two-phase flow inside the atomizer. The bubbly flow inside the atomizer has been reported to provide spray steadiness, while slug flow contributes to the pulsation and unsteadiness in the spray. Bubble breakers are effective devices to break large bubbles into smaller ones. The bubble breakers used previously in the effervescent atomizer are porous media and perforated inserts. The present study is focused on investigating the influence of a new type of bubble breaker in an effervescent atomizer. The specific focus will be on the effect of bubble breaker and its various configurations, on the internal two-phase flow and the spray characteristics over a range GLRs.

## 4.2 Experimental setup and techniques

### 4.2.1 Effervescent atomizer

An effervescent atomizer with full optical access was designed and fabricated for this study, which enabled direct visualization of the two-phase flow inside the atomizer. The atomizer comprised of gas and liquid inlets, atomizer body, an aerator tube, and an exit orifice, as shown schematically in Figure 4-1. The atomizer body was made of 3 mm thick acrylic tube with the inner diameter of 9.6 mm. The configuration of the Effervescent atomizer was inside-out, i.e., an aerator tube was placed inside the atomizer

body, which allowed the gas to exit from the aerator holes and generate bubbles in the annular region (1.6 mm thick) where the liquid was flowing. The bubbles generated through the aerator holes, travel downstream with the liquid cross-flow into the mixing zone. This bubble-liquid mixture then passed through a 90° convergent section and exited through the bottom orifice to produce spray. The diameter and length of the bottom orifice were 1.27 mm and 6.35 mm, respectively (see Appendix A for the detailed drawings of the atomizer).

Due to the circular cross-section of the atomizer body, direct imaging of the flow would result in significant image distortion. Thus, the atomizer was placed inside a 1.5 mm thick square acrylic tube 25.4 mm × 25.4 mm in cross-section to offset atomizer body's curvature effect. To compensate for the image distortion, the space between the atomizer tube and the square channel was filled with water. The lower portion of the mixing zone and the convergent section were machined directly into an acrylic block with square cross-section. The designed effervescent atomizer has the flexibility to replace the aerator tube as well as vary its position inside the atomizer body, which in turn allows changing the length of the mixing zone.

#### 4.2.2 Aerator tube

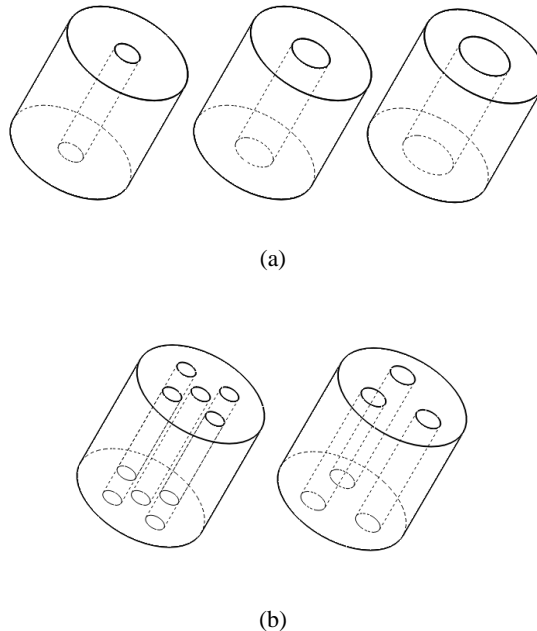

In the present study, the aerator tube with multi holes was considered to investigate the effect of bubble breakers. The aerator tube was built with a conical base. It has four columns of aerator holes, 90 degrees apart. The holes were offset by 4 mm in adjacent columns. The aerator tube was made from brass tube with inner diameter of 5.3 mm, the outer diameter of 6.3 mm and the holes diameter of 0.52 mm.

**Figure 4-1: Schematic of the effervescent atomizer used in the study (not to scale).**

### 4.2.3 Bubble breakers

To improve the size and distribution of the bubbles approaching the exit orifice, bubble breakers were used inside the mixing zone upstream of the exit orifice. Five bubble breaker inserts with different hole configurations were considered which allowed to investigate the impact of the size and number of holes on the bubbles fragmentation and consequently the spray quality. All breakers were made from acrylic and have a cylindrical shape with the outer diameter and length of 9.5 mm and 10 mm, respectively. The effect of the size of the breaker hole on the bubble fragmentation was investigated for breaker with a single-hole at the center. Three breakers of this configuration were built with the hole-diameter of 2 mm, 3.18 mm and 5 mm, (see Figure 4-2(a)). For the investigation of the impact of number of holes, three breakers were considered with one, three and five holes with the hole-diameter of 3.18 mm, 1.83 mm and 1.42 mm, respectively (see Figure 4-2(b)). Note that, the total flow area for each of these breakers were the same (see Appendix B for the detailed drawings of bubble breakers).

**Figure 4-2: Schematic of the bubble breaker used in the study (a) Single-hole bubble breakers, (b) Multi-hole bubble breakers.**

#### 4.2.4 Experimental setup

Figure 4-3 shows the schematic and photograph of the experimental setup used in this study. The atomizer was mounted on a stand made from steel bars. In the present study, water and air were used as liquid and gas phases, respectively. The flow rate of water was measured and controlled by a rotameter (FL-4205, Omega Engineering) which was installed upstream of the inlet valve of the atomizer. Compressed air from the main supply line was used as the supply air. To avoid pressure fluctuations and maintain a uniform air pressure at the atomizer inlet, the air from the main supply line first passed through a settling chamber to dampen any line pressure fluctuations, and then through a narrow tube to the atomizer. A rotameter (FL-1448-G, Omega Engineering) installed upstream of the atomizer was used to measure and control the air flow rate (see Figure 4-3(a)). The uncertainties in the measurement of liquid and gas flow rates were  $\pm 0.03$  and  $\pm 0.035$  lpm, respectively. Water and air pressures were measured via pressure gauges mounted downstream of the respective rotameters.

## 4.2.5 Visualization and measurement technique

### 4.2.5.1 Internal flow

The transparency of the atomizer and the correction for the curvature effects allowed the visualization of the internal two-phase flow. A high speed imaging system was used to capture the images of the flow regime inside the atomizer, which was comprised of a high-speed camera (Photron SA5) with 60 mm lenses. The imaging system was controlled via Photron FASTCAM Viewer software through a PC. Back-lit shadowgraphy technique was used for imaging, which was comprised of a 500W halogen lamp and a diffusion screen placed behind the atomizer (see Figure 4-3(a) and (b)). In the present study, the liquid flow rate ranged from 0.757 to 1.135 lpm and the gas flow rate ranged from 0.6 to 4.82 lpm (GLR ranged from 0.53 to 9.55). For all configurations, 14000 images were captured at a rate of 20000 frames per second at each GLR. At this frame rate, the resolution of the camera was  $704 \times 520$  corresponding to  $40 \text{ mm} \times 30 \text{ mm}$ . An In-house algorithm developed in the Matlab environment was used to measure the bubble size and compute bubble size distribution. The uncertainty in measuring the bubble size is within  $\pm 1$  pixels, which correspond to the uncertainty of  $\pm 0.05 \text{ mm}$ .

### 4.2.5.2 External flow (Spray)

The same imaging system was used to capture the images of the spray droplets. However, the 60 mm lens was replaced by a 12X zoom lens. Due to the high velocity of the droplets, the camera frame rate was set at 150,000 frames per second. At this frame rate, the camera resolution was reduced to  $256 \times 144$ , corresponding to the field of view of  $3.1 \text{ mm} \times 5.6 \text{ mm}$ . Due to a smaller field of view and higher frame rate, a continuous Diode-Pumped Solid-State laser (LRS-0532, Laser Glow Technologies) was used for back-lit shadowgraphy (see Figure 4-3(c)). The laser output was connected to a conical lens via a fibre optic cable, which produced a light cone. The measurements were made at an axial location of 150 mm downstream from the exit orifice, where the spray was fully developed [19]. To break any interference effects in the spray and randomize the spray pattern at each GLR, 10 sets of measurements were made at different times. 5000 spray

images were captured in each set. An in-house algorithm in the Matlab environment was used for droplet detection and quantification, which automatically detects and tracks the spray droplets and computes various droplet characteristics such as the droplet cross-sectional area, perimeter and corresponding equivalent diameter, and velocity. The uncertainty of detecting the droplets was within  $\pm 2$  pixels, which correspond to the uncertainty of  $\pm 0.04$  mm.

### 4.3 Results and Discussion

Figure 4-4 illustrates the impact of the new insert (bubble breaker) on the bubble size in the mixing zone of the atomizer by qualitatively comparing the two-phase flow with the atomizer without a bubble breaker, for three different GLRs. The results show a clear impact of the breaker on the bubble size reduction. For the case without the bubble breaker, the results show the classical two-phase flow regimes inside the mixing zone of the atomizer. That is, at the low GLR, bubbly flow is observed and with an increase in the GLR, it changes to the slug flow at the medium GLR and then to the annular flow at the high GLR. The bubble size also increased with an increase in the GLR. When a single-hole breaker is placed, it influenced the bubble size not only inside the breaker but also in the area upstream of the breaker. It is observed that the bubble breakup already started in the upstream zone and was further extended when these bubbles entered the breaker. At the lowest GLR of 0.53 (Figure 4-4(a)), the results show that most of the bubbles were already broken to a size smaller than the diameter of the bubble breaker hole and hence relatively fewer bubbles underwent further breakup. These bubbles were significantly smaller in size compared to those present in the mixing zone without the breaker. The sudden contraction of the flow at the bubble breaker causes a local increase in the velocity and also velocity gradients. This shear flow of the liquid is likely the dominant mechanism for the upstream bubble breakup [34]. The presence of the conical base of the aerator tube also plays a role in streamlining the flow and causing the bubble stretching which further supports the bubble breakdown.

Figure 4-4(b) shows the flow behavior in the atomizer with and without the bubble breaker at the GLR of 3.17. For the case without the breaker, the image shows large bubbles and some of those were of the same size as the mixing zone diameter. For larger bubbles, the impact of the liquid acceleration in the converging section upstream of the bubble breaker became more prominent. That is, the bubbles started to elongate in that region due to the strong liquid shear. The sudden contraction also induced a liquid velocity component in the horizontal direction immediately above the bubble breaker. As the elongated bubbles try to negotiate sudden contraction, they further stretched and formed a “neck” at the bubble breaker entrance. This neck often breaks due to the sharp edge at the entrance or due to the horizontal liquid velocity component. Hence, the bubbles normally started to break as they enter the breaker. The small-size bubbles that enter the insert without breaking could break inside the insert due to the interaction of shear and surface tension forces. Comparison the bubble size at this GLR clearly shows that the bubble breaker effectively broke large bubbles into smaller sizes.

At the highest GLR of 9.55, the flow is predominantly annular in the absence of the bubble breaker. When the bubble breaker is placed inside the mixing zone, the flow behavior changed significantly in the region upstream of the bubble breaker. The liquid film that is formed on the outer wall of the atomizer hit the bubble breaker and hence, diverted. This diversion of the liquid interacts with the core gas flow and changes the structure of the two-phase flow. It is observed that bubbles are formed in this region as well as the unsteady fluctuations of the gas-liquid interface. The flow then enters the breaker hole and induces highly unsteady slug-annular flow that often breaks into a mixture of deformed bubbles with different sizes. The above results clearly demonstrate that the given breaker facilitate the bubble breakup over the given range of GLRs.

**Figure 4-4: Effect of bubble breaker on the flow behavior in the mixing zone upstream the exit orifice at different GLRs (a) GLR=0.53, (b) GLR=3.17, (c) GLR=9.55. In each image pair, left image presents the case with breaker and right image presents the case without breaker.**

#### 4.3.1 Effect of bubble breaker single-hole diameter

The results in the preceding section compare the two-phase flow with and without the bubble breaker. In this section, the influence of the size of the bubble breaker hole on the two-phase flow behaviour is compared. Figure 4-5 shows the results for three different single-hole diameters (opening area) of the bubble breaker at three different GLRs. It is observed that at a given GLR, the size of the breaker hole has an impact on the bubble breakup. At the low GLR of 0.53 (Figure 4-5(a)), the bubbly flow is observed upstream of the bubble breaker while it is fragmented into smaller-size bubbles through the breakers for all three sizes of the breaker hole. A quick comparison shows that a decrease in the size of the breaker hole leads to the generation of smaller bubbles in numerous quantities. This is due to the reason that with a reduction in the cross-section area of the flow, the velocity and the velocity gradient increase which enhance the bubble breakup

frequency and result in smaller size of bubbles. It is also observed that a reduction in the breaker-hole diameter results in a large number of small bubbles homogeneously distributed in the convergent section approaching the exit orifice. This contributes to the reduction in the unsteadiness of the internal two-phase flow in the convergent section (bottom of the mixing zone) that arises due to the presence of liquid or gas-liquid flow in the exit orifice. This unsteadiness in the flow approaching the exit orifice results in the pulsation and large ligament formation in the spray, which leads to inefficient atomization [14].

As the GLR increased, the size of bubbles upstream of the bubble breaker increases and hence, the size of bubbles inside the bubble breaker also increases (see Figure 4-5(b)). The smaller bubble breaker hole still shows more effective bubble breakup compared to the larger size of breaker hole. At this GLR, the regime is the slug flow in the absence of the bubble breaker (see Figure 4-4(b)). In the presence of bubble breaker, the slug flow is still observed inside the bubble breakers of all three diameters. However, the size of the bubbles is controlled by the diameter of the bubble breaker hole. The behavior in the convergent section is similar to that at the low GLR for the three bubble breaker diameters. However, the overall size of the bubbles is increased at this GLR. The results also indicates that with an increase in the size of the bubble breaker hole, the chances of the presence of liquid-only-phase inside the convergent section and the exit orifice increase, which result in spray pulsation.

At the highest GLR shown in Figure 4-5(c), the flow in the absence of the bubble breaker is the annular flow. In the presence of the bubble breaker, the flow upstream of the bubble breaker tends to form bubbles however, this effect diminishes with an increase in the breaker-hole diameter. The flow inside the small-diameter bubble breaker is at a high velocity and the flow features are not clearly evident. However, the bubble breakup is still observed in the entrance region of the bubble breaker. With an increase in the size of breaker hole (medium diameter case), the unsteady slug-annular flow is observed inside the hole which often changes into bubbly flow due to breakdown of the pressure balance at the gas-liquid interface and hence, effect the flow structure. The bubble fragmentation is still observed at the entrance of the breaker-hole while, the size of the fragmented

bubbles are larger compared to the small-diameter hole, as expected. A further increase in the size of the breaker-hole (large diameter case) results in an unsteady annular flow inside the bubble breaker. In the convergent section, bubbles were observed for the small and medium breaker-hole diameter cases indicating that the slug-annular flow breaks down to the bubbles. For the largest breaker-hole case however, an almost continuous annular flow is observed from the upstream of the bubble breaker to the exit orifice. A detailed inspection of the images for these cases indicates that the flow unsteadiness upstream of the bubble breaker induces interfacial waves that when enter the bubble breaker hole, causes the annular flow to be deformed and disintegrated into many bubbles.

**Figure 4-5: Effect of bubble breaker hole diameter at different GLRs (a) GLR=0.53, (b) GLR=3.17, (c) GLR=9.55.**

As mentioned earlier, the bubble fragmentation or breakup is a process by which a bubble splits into two or more bubbles i.e. the disintegration of a large bubble into many smaller bubbles. Surface tension always acts to maintain the bubble-liquid interface stable while the shear and pressure forces (disruptive force) acts to deform and disrupt it. Once the shear and/or pressure forces become large enough, the surface tension is not able to retain the bubble-liquid interface stable and the breakup occurs [27]. In the present study, the presence of single-hole bubble breaker results in two different types of bubble breakups. In the first type, the bubble fragmentation occurs at the entrance of the bubble breaker primarily due to the dominant effect of the shear stress from the liquid flow. To obtain a better insight into the bubble breakup process of this type, a sequence of images are shown in Figure 4-6(a) to illustrate the process as a function of time. As the figure shows, in the region upstream of the breaker, the flow converges and strong velocity gradients are introduced. The sudden area change also causes pressure losses and hence introduces additional pressure gradient. The shear drag, which is the dominant force elongates the bubble and often forms a neck, as seen in Figure 4-6(a). The pressure drag does not contribute to the elongation of the bubble and hence, it is expected that its contribution is limited to pushing the bubbles along the liquid stream. The image sequence also indicates that the bubble neck breaks when the breaker-hole has fewer bubbles. As the number of bubbles inside the hole increases, the bubble elongates but the neck does not break. This could be due to the reason that an increase in the number of bubbles inside the breaker-hole increases the liquid blockage, which causes a local pressure rise, which reduces the local drag force on the bubble.

At the lowest GLR, for the smallest size of the bubble breaker, most of the bubbles are fragmented at the entrance due to the high shear stress. However, with an increase in the diameter of the bubble breaker hole, the shear stress decreases and hence the rate of bubble breakup reduces. It is also observed that as the hole-diameter increases, bubbles larger than the breaker-hole elongate into the hole and a neck is formed which further fragments at the entrance or inside the hole. The results also show that for the medium- and large-hole breakers, bubbles with the smaller size than the size of bubble breaker hole normally do not fragment at the entrance of the hole. This could be due to the reason

that as the bubble size reduces, the magnitude of shear stress acting on it also decreases and hence, the elongation effect diminishes.

The second type of breakup occurs inside the bubble breaker, when the size of bubbles is relatively small compared to the diameter of the bubble breaker hole. Figure 4-6(b) depicts this breakup process for two bubbles (marked with dashed outline) in the bubble breaker hole. As the image sequence shows, these bubbles deformed and broke into a group of smaller bubbles. Some bubbles completely detached from the group, while some independent small bubbles coalesced with the group. The shear drag force still plays a major role in the bubble breakup. It should also be noted that the sharp edge of the bubble breaker-hole causes a flow separation into the breaker-hole, which likely induces vortex shedding. These shedded turbulent vortices also contribute the bubble breakup [35]. Further downstream, this group of bubbles when entering the convergent section is often disintegrated due to the velocity gradients.

The detailed analysis of the data also shows that the same bubble may undergo these two types of bubble breakups. Figure 4-6(c) illustrates this double breakup process. As seen in the figure, a bubble elongates and breaks at the entrance region and then it undergoes further breakup during its passage through the bubble breaker hole. The data analysis also shows that if a long slug bubble or annular flow inside the bubble breaker becomes unsteady, gas-liquid interface starts to fluctuate and causes the breakup. The slug bubble may choke the hole of the bubble breaker and the exit orifice at the same time, which results in a sudden closing. The sudden closing of the single-hole bubble breaker leads to a sudden velocity reduction and a pressure pulse upstream causing the bubble deformation and fragmentation. Similar trend has been observed in a previous study for the two-phase flow approaching the exit orifice [15].

**Figure 4-6: Image sequences showing the mechanism of bubble breakup in single-hole bubble breaker. (a) First type of bubble fragmentation at the entrance,  $GLR=0.53$ ,  $\Delta t=0.75$  ms, (medium hole). (b) Second type of small-size bubble fragmentation inside the bubble breaker,  $GLR=0.53$ ,  $\Delta t=0.2$  ms (large hole) (c) Double breakup,  $GLR=0.53$ ,  $\Delta t=0.25$ ms (medium hole).**

Figures 4-4, 4-5 and 4-6 qualitatively provide the depiction of the bubble breakup processes for the single-hole bubble breaker and the influence of the breaker-hole diameter on the bubble size as well as the visual comparison of the two-phase flow in the mixing zone with and without the breaker. To obtain quantitative estimates, the size of individual bubbles was measured. As mentioned in the Experimental setup section, an algorithm was developed to measure the vertical extent of each bubble, which is considered as the characteristics bubble size. The bubble size distribution inside the breaker-hole for different hole diameters is shown in Figure 4-7(a) and (b) at the GLR of 0.53 and 3.17, respectively, under the same operating condition as in Figure 4-5. Note that the data for the reference (without the bubble breaker) case is based on the bubbles present in the entire mixing zone. The bubble size distribution is presented in the form of Probability Density Function (PDF).

At the low GLR, it is observed that the smallest hole-diameter results in a narrower band of bubble size compared to the other two diameters. With an increase in the size of the hole, the bubble size distribution bandwidth increases. The bubble distribution tail on the right side represents the longer bubbles, which are associated with the vertical elongation of bubbles inside the breaker hole. In comparison with the reference case (without the bubble breaker), the results show that the overall bubble size distribution shifts to the right without the bubble breaker, i.e. larger bubbles, as observed qualitatively in Figure 4-4. The bubble size distribution at the GLR of 3.17 is shown in Figure 4-7(b). The results show that the distribution trends are similar to that at the low GLR, however, the distributions in general, are shifted to the right. The small-hole bubble breaker has the narrowest distribution, while the presence of elongated bubbles increased with an increase in the breaker-hole diameter. Figure also shows that the bandwidths of the bubble size distribution at the mid height of the distribution are 1.1 mm, 1.7 mm, 2 mm and 2.4 mm for small, medium, large size breaker-holes and for the case without bubble breaker, respectively. This indicates that the bubble size range decreased by 54%, 30% and 17% for the small, medium and large size breaker-hole compared to the reference case without breaker, respectively. The results also show a more distinct shift of the bubble size distribution to the right in the absence of the bubble breaker, compared to that at the low GLR. Figure 4-7(c) shows the bubble size distribution at the high GLR of 9.55. It is observed that the slug-annular region is formed within the bubble breaker hole (see Figure 4-4(c) and 4-5(c)). Thus, the bubble size distribution bandwidth increases and a longer tail on the right side of the distribution is formed almost for all cases. The results also show that the small-hole bubble breaker, at this GLR also has the narrowest bubble distribution bandwidth similar to that for the low and medium GLRs, as mentioned earlier. The results also illustrate that with an increase in the size of the bubble breaker-hole, the bubble size distribution bandwidth increases and the peak shifts towards the right i.e. the bubble size increases.

The mean bubble size for the three breaker-hole diameters at different GLRs is shown in Figure 4-7(d). The results show that the novel bubble breakers generate smaller bubble at all GLRs. It is also observed that with an increase in the GLR, the mean bubble size increases for all cases. However, the rate of increment of the bubble size in the presence

of bubble breaker is less than that for the case without the bubble breaker. The average size of bubbles inside the bubble breakers at GLRs of 0.53, 3.17 and 9.55, are 1.35 mm, 1.98 mm and 2.36, respectively, which are 24%, 34% and 61% smaller than the mean bubble size relative to the case without the breaker. It is found that at GLRs of 0.53, 3.17 and 9.55, the mean bubble size in the smallest bubble breaker hole is 18%, 26% and 27% smaller than the overall average bubble size in the medium- and large-hole bubble breakers, respectively. The results show that the presence of the single-hole bubble breaker promotes the bubbly flow inside the atomizer by generating small bubbles.

(d) Mean bubble diameter ( $D_B$ ) inside the bubble breakers versus  $GLR$ . Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

Earlier results have shown that the single-hole bubble breaker effectively breaks large bubbles into small ones. It has also been illustrated that by decreasing the breaker-hole diameter, more uniform and smaller bubbles are produced. Since the end product is the spray, it is important to investigate the impact of these single-hole bubble breakers on the spray quality. As mentioned in the Experimental setup section, the spray behavior is characterized based on the droplet size and velocity obtained from the analysis of the image data of the spray using an in-house algorithm. Figures 4-8 and 4-9 illustrate the spray characteristics (i.e. droplet size and droplet velocity in the form of mean and distribution) correspond to the same cases that illustrate the internal two-phase flow behavior in Figure 4-5 (qualitatively) and Figure 4-7 (quantitatively). Figure 4-8(a) shows the distribution of the droplet size at low  $GLR$  of 0.53 for different sizes of the bubble breaker hole and the reference case without the breaker. The figure indicates that the atomization process with and without the bubble breaker results in a relatively similar

droplet size distribution at low GLR. As the GLR increases to 3.17, the results show that the smallest size of bubble breakers produces slightly narrower droplet size distribution (see Figure 4-8(b)). At the higher GLR of 9.55 (see Figure 4-8(c)), a clear effect of breaker-hole size on the droplet size is observed. It is illustrated that with a reduction in the size of the bubble breaker hole, the droplet size distribution band tends to become narrower.

Figure 4-8(d) summarizes the results in the form of mean droplet diameter for all cases. The results show that an increase in the GLR results in smaller droplets size, which is consistent with previous studies [16, 19, 21]. It is also observed that over the given range of GLRs, the atomizer with the bubble breaker is able to produce smaller droplet size compared to the case without a bubble breaker. The effect is more prominent for the small breaker-hole, where on average, the droplet sizes are 7% smaller than that for the case without the bubble breaker for the given GLR range. For the medium and large breaker-holes, the droplet sizes are quite comparable but still lower than that for the case without the bubble breaker, on average by 4% over the given GLR range.

Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

Figure 4-9 shows the spray behavior in the form of mean and distribution of the droplet velocity for the atomizer with and without the bubble breaker (corresponding to the results shown in Figure 4-8). The results show a unimodal distribution of droplet velocity for all cases, which is expected and reported in previous studies [21, 36]. At the lowest GLR of 0.53 (Figure 4-9(a)), it is observed that with a decrease in the size of bubble breaker-hole, the velocity distribution is shifted to the right except for the largest breaker-hole diameter, which has similar distribution as for case without the bubble breaker. This trend indicates that the droplet velocities increased with a reduction in the hole-diameter of the bubble breaker. At higher GLRs (see Figure 4-9(b) and (c)) similar trends were observed. However, at the highest GLR of 9.55 the droplet velocity distributions for the

medium- and small-size hole were similar. Figure 4-9(d) shows the summarized results in the form of normalized mean droplet velocity. The mean droplet velocity is normalized by  $V_{La}$  which is the liquid velocity in the liquid inlet of the atomizer. The results illustrate that small and medium breaker-holes increase the mean drop velocity compared to the case without the bubble breaker. At the lowest GLR, the mean droplet velocity for small and medium holes is about 10% higher than the case without the bubble breaker, which increased to 13% at the highest GLR. The results however, show that the mean droplet velocities for the largest breaker hole are comparable with that for the case without the bubble breaker.

#### 4.3.2 Effect of number of holes in the bubble breaker

In the previous section, a bubble breaker with a single hole in the middle was considered and the influence of the hole-diameter was investigated. In this section, bubble breakers with multiple holes are considered and the influence of the number of holes on the bubble breakup process and spray quality is investigated. The bubble breaker inserts with three and five holes are considered, with the hole-diameters of 1.83 mm and 1.42 mm, respectively. The configurations of these holes in the bubble breakers are shown in Figure 4-2(b). The reference single-hole bubble breaker considered for comparison has the hole-

diameter of 3.18 mm. Note that the total cross-sectional area of hole openings (i.e. the total flow area) for all three configurations was kept the same.

Figure 4-10 shows the effect of number of breaker holes and the holes configuration on the bubble fragmentation at different GLRs. At the low GLR of 0.53 (see Figure 4-10(a)), the bubbly flow is observed in the region upstream of the bubble breaker for all three breakers. However, the comparison shows that the configuration of the bubble breaker influences the upstream two-phase flow behavior. The size of upstream bubbles was smallest for the single-hole breaker, which increased for the five-hole breaker and the largest upstream bubbles were observed for the three-hole breaker. A plausible explanation for this trend is that for the single-hole breaker, the hole was in the middle and aligned with the conical base of the aerator tube. Hence, the flow was streamlined and accelerated through the middle-hole with strong velocity gradients. As mentioned earlier, these strong velocity gradients are responsible for the upstream bubble breakup due to the rupturing of the bubbles by the shear. Thus, small bubbles are generated in this configuration.

For the five-hole bubble breaker, the middle-hole aligned with the conical base of the aerator tube while the four other holes were in the peripheral region (see Figure 4-2(b)). This influenced the flow pattern in the upstream region, which include the flow diversions. The flow through the middle-hole was still streamlined with high velocity gradients but the flow diverted to the peripheral holes was expected to have relatively small velocity gradients due to the flow diversions. This is confirmed by a careful inspection of the image for this case, which shows that in the upstream region close to the hole, the flow near the center has smaller bubbles compared to those in the peripheral regions. Furthermore, the hole-diameter was much smaller in this configuration which caused the flow acceleration locally in the immediate vicinity of the hole-opening and the bulk of the upstream flow was not significantly affected. That is, the high shear was produced in the close vicinity of the hole-entrances. This effect is also clearly evident in the image. For the three-hole breaker, no hole was located in the middle and hence the flow was diverted and hence the velocity gradients were smaller. Thus, the weak shear in the bulk flow was not very effective to break upstream bubbles. The local flow

acceleration and strong shear in the close vicinity of the hole-entrances is evident in the corresponding image.

Although the multiple holes in the breaker were not very effective in breaking the upstream bubbles, the results show that these breakers however, generated smaller bubbles inside the breaker holes. As mentioned above, the multi-hole breaker produced strong shear at the entrance of each hole, which effectively contributed to the bubble rupture and breakdown at the hole-entrance. Hence, despite being unbroken in the upstream region, these bubbles were effectively broken at the hole-entrance, which is clearly visible in the images that highlights the stretching of bubbles at the hole entrance. The strong local shear produced at the hole-entrance is also a function of the hole-diameter, which decreased with an increase in the number of holes. Hence, the breakup of the bubbles was more effective for the five-hole breaker, which has the smallest hole-diameter. In addition, the smaller hole-diameter also restricts the lateral extent of the bubbles as they flow through the holes.

As GLR increases to 3.17, the size of bubbles upstream of the breaker increases, which increases the size of the bubbles inside the bubble breaker as well. However, the trends were similar to that observed at the low GLR (see Figure 4-10(b)). The results show that slug bubbles are observed inside the breaker-holes for all cases. Similar to the low GLR case, the five-hole bubble breaker due to smaller size of holes was found to be more effective in the bubble breakup. The results also show that the chances of the bubbles coalescence inside the holes increases with an increase in the GLR for both multi-hole breakers. With a further increase in the GLR (see Figure 4-10(c)), the influence of multi-hole configurations on the upstream bubble breaker tends to diminish. The flow inside the the bubble breakers (single-hole and multi-hole) changes to the slug-annular flow. The results show that the unsteady annular region observed in the single-hole breaker is also observed in the multi-hole breakers. However, the rate of unsteadiness slightly decreased in the multi-hole breakers compared to the single-hole breaker. This is likely due to a decrease in the chances of the blockage of the bubble breaker holes and the exit orifice by the bubbles, with an increase in the number of holes and a decrease in the size of bubbles inside the convergent section.

**Figure 4-10: Effect of number of holes in the bubble breakers at different GLRs, (a) GLR=0.53, (b) GLR=3.17, (c) GLR=9.55.**

The above results show that multi-hole breakers lead to the generation of smaller fragmented bubbles compared to the single-hole breaker (medium size). It is also observed that the size of bubbles inside the mixing zone is larger than the diameter of the multi-hole bubble breakers and the strong shear at the entrance causes the bubble fragmentation into small bubbles or a chain of small bubbles whose sizes are controlled by the hole-diameter. The chain of bubbles may further fragment into many smaller bubbles or coalesce and form elongated bubbles. The elongated bubbles typically have wavy interface, which promotes further breakup inside the convergent section at the bottom of the mixing zone.

As discussed earlier, the primary mechanism of bubble fragmentation in multi-hole breakers is the strong shear at the hole-entrance and smaller hole-diameter. Sequences of images for the three-hole and five-hole bubble breakers are shown in Figure 4-11 (a) and (b), respectively, that depict this mechanism with a better insight. The further breakup of small bubble inside the hole found in the single-hole breaker (see Figure 4-6(b)) is not observed in the multi-hole breaker, which is likely due to the smaller size of fragmented bubble. Figure 4-11(c) illustrates the further breakdown of the bubbles into the convergent section after passing through the breaker holes. Once the bubble inside the hole exits the breaker, it experiences lower liquid velocity so the shape of bubble changes to the spherical form due to the liquid drag force (pressure drag force). Then due to the effect of the liquid shear force inside the convergent section, the bubble elongates into the flow direction and fragments into small-size bubbles. The results show that for the five-hole breaker, more bubble elongations in the convergent section through the exit orifice are observed for the bubbles that exit from the peripheral holes compared to those that exit from the central hole. This is likely due to the longer distance between the bottom of the hole and the exit orifice and correspondingly higher shear stress due to the wall effects, which results in further bubble elongation causing more bubble fragmentations.

(a) Penetration and fragmentation of a bubble into two holes for the three-hole bubble breaker (b) Penetration and breakup of bubbles either from one hole or number of holes in the five-hole bubble breaker. (c) Bubble fragmentation inside the bottom convergent section. GLR=0.53.**

Results presented earlier in the section provide a qualitative description of the bubble breakup process in multi-hole breakers in comparison with a single-hole breaker. The bubble size was measured in the images for these cases using the algorithm mentioned earlier. Figure 4-12 illustrates the bubble size inside the bubble breakers correspond to the cases shown in Figure 4-10. The bubble size distributions for breaker with different number of holes (same total opening area) and the case without the bubble breaker are shown in Figure 4-12(a), (b) and (c) at GLRs of 0.53, 3.17 and 9.55, respectively. Plots clearly show the effect of number of breaker holes on the bubble size distribution for all

GLRs. It is observed that with an increase in the number of holes, the peak of the bubble size distribution shifts towards the left, i.e. the mean bubble size decreases. The results also show that with an increase in GLR, the bubble distribution bandwidth increases and a longer tail on the right side is formed almost for all cases. This tale is associated with the elongated or slug bubbles present in the flow.

The mean bubble size for a given rang of GLRs is presented in Figure 4-12(d) for different bubble breaker configurations. It is observed that with an increase in GLR, the bubble size inside the bubble breaker increases, as expected. The results also show that the multi-hole breakers produce smaller bubbles compared to the single-hole breaker (medium size breaker) over the given GLR range. The mean bubble size for three- and five-hole breakers is quite comparable. The results show that three- and five-hole breakers produce bubbles that are on average 31%, 13% and 22% smaller than that in the single-hole breaker at GLRs of 0.53, 3.17 and 9.55, respectively.

(d) Mean bubble diameter ( $D_B$ ) inside the bubble breaker versus  $GLR$ . Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

The impact of the number of breaker holes on the bubble fragmentation is presented in Figures 4-10 to 4-12. As mentioned earlier the bubble size increases with an increase in  $GLR$  and decreases with an increase in the number of bubble breaker holes. The influence of the number of bubble breaker holes on the droplet size is shown in Figure 4-13. The droplet size distributions for the lowest  $GLR$  of 0.53, for three different breaker configurations and for the case without the the bubble breaker are illustrated in Figures 4-13(a). The figure indicates that the atomization process with and without the bubble breaker results in a relatively similar droplet size distribution at low  $GLR$ . As the  $GLR$  increases to 3.17, the results show that the multi-hole breakers produce slightly narrower droplet size distribution (see Figure 4-13(b)). At the highest  $GLR$  of 9.55 (see Figure 4-13(c)), a clear effect of bubble breakers on the droplet size is observed. It is illustrated

that with an increase in the number of breaker-hole a narrower band of droplet size is produced. That is, at the highest GLR, the effect of the number of bubble breaker hole becomes more significant. Figure 4-13(d) presents the mean droplet size for different breaker configurations over the given range of GLR. The results show a distinct effect of single- and multi-hole bubble breakers on the mean droplet size. It is observed that the droplet size decreases monotonically with an increase in the number of breaker holes over the entire range of the GLRs. At the lowest GLR of 0.53, the three- and five-hole breakers show almost similar droplet size, but with an increase in GLR, the five-hole breaker produced the smallest droplet size. It is observed that the atomizer with multi-hole bubble breakers (three- and five-hole) produced on average, 8% smaller droplets than the atomizer without a breaker over the given GLR range. In comparison, the atomizer with equivalent single-hole breaker produced on average 4% smaller droplets compared to the atomizer without a breaker for the same range of GLR.

Error bars (based on the standard error of the mean) are smaller than the size of the symbols.**

The corresponding droplet velocity distributions are shown in Figure 4-14 (a-c) for the given range of GLRs. At the lower GLR of 0.53, the results show the clear effect of bubble breakers on the velocity distribution. It is observed that with an increase in the number of holes from single-hole to three-hole, the velocity distribution is shifted to the right, i.e. the droplet velocity increases. However, the velocity distribution trends for the three- and five-hole breakers are very similar. This is likely due to the reason that at this GLR, the two-phase flow inside three- and five-hole breakers shows small bubbles with almost the same mean bubble size (see Figure 4-12(d)), which affects the spray droplet size and velocity as well. The results also illustrate the variation in the velocity distribution at higher GLRs (Figure 4-14(b) and (c)). At the highest GLR, the results show a relatively flat distribution for the five-hole breaker case. This effect is also present

for the three-hole breaker as well but not very prominent. This flatness of the velocity distribution is associated with higher uncertainty in estimating the droplet velocities at the highest GLR. Hence, the droplet velocity values for these cases should be interpreted with caution. The normalized droplet velocity for different breaker configurations and the non-breaker case at various GLRs is shown in Figure 4-14(d). The results show that with an increase in the GLR, the droplet velocity increases for all cases. At the low GLR, the comparison among different bubble breakers and the reference case shows similar droplet velocities however, with an increase in GLR, the droplet velocity in general, increased for the cases with the bubble breaker. The above results show that the multi-hole breakers provide a relatively finer spray with higher velocity over the given range of GLRs. However, it should be noted that the multi-hole breakers increase flow losses and hence higher pressure drop at the atomizer exit is expected.

## 4.4 Conclusion

An experimental study was conducted to investigate the effect of bubble breaker inside an effervescent atomizer on the internal and external two-phase flow. A new type of bubble breaker with different configurations (size and number of holes) was considered over a range of GLRs from 0.53 to 9.55. A high-speed imaging technique was used to capture the two-phase flow images, which were then processed with an in-house algorithm to compute various characteristics of bubbles and droplets. It was observed that with an increase in GLR, the size of bubbles upstream of the breaker increases and consequently, the size of bubbles inside the breaker also increases. The results show that with an increase in GLR, the spray droplet size and velocity increases for all cases. The

results also illustrate a clear impact of the novel bubble breaker on the bubble size reduction, i.e. the bubble breaker effectively fragments large bubbles into smaller ones. It was found that the novel bubble breaker reduces the bubble size by 15% to 67% for various configurations and GLRs.

It was illustrated that the size of the bubble breaker hole has an impact on the bubble size inside the breaker hole and the spray droplet characteristics over the given range of GLR. The results show that the single-hole breaker effectively breaks large bubbles into small ones due to the dominant effect of the shear stress from the liquid flow at the entrance of the bubble breaker and shedded turbulent vortices inside the hole. At different GLRs, it was illustrated that by decreasing the breaker-hole diameter, more uniform and smaller bubbles are produced. It was also observed that over the given range of GLR, the atomizer with the bubble breaker was able to produce smaller droplet size compared to the case without a bubble breaker. The effect is more prominent for the small breaker-hole, where on average, the droplet sizes are 7% smaller than that for the case without breaker for the given GLR range.

Number of holes of the breaker (same total flow area) was also found to have an impact on the internal and external two-phase flow behavior. The results show that the multi-hole breaker produced strong shear at the entrance of each hole, which effectively contributed to the bubble elongation and breakdown at the hole-entrance. It was observed that multi-hole breakers lead to the generation of smaller fragmented bubbles compared to the single-hole breaker with the same total flow area at different GLRs. It was also observed that the droplet size decreases monotonically with an increase in the number of breaker holes over the given range of GLR. The results show that the multi-hole breakers provide a relatively finer spray (8% smaller droplets than that in the case without bubble breaker) with higher velocity. It is concluded that the atomizer with the bubble breaker exhibits higher spray steadiness and more effective atomization compared to the atomizer without the bubble breaker.

## 5 Conclusions and Recommendations

### 5.1 Overall Conclusions

Effervescent or "aerated-liquid" atomization is a twin-fluid atomization technique in which the low-velocity gas is injected into the flowing liquid, upstream of the exit orifice and this injected gas in the form of bubbles inside the liquid, provides a good atomization. The effervescent atomization process and consequently the characteristics of the resulting spray are dependent on the atomizer internal geometry and operating conditions. The present research, which was conducted in two parts, studied the dynamics of bubble formation in a liquid cross-flow and the two-phase flow behavior in an effervescent atomizer.

To gain a better insight into the fundamental bubble formation process, an experimental study was reported in Chapter 2 that investigated the bubble formation from a novel nozzle design in a liquid cross-flow using a high-speed imaging system. The main focus was to investigate the impact of the configurations and orientations of this novel nozzle on the bubble formation and detachment process in a liquid cross-flow over a range of GLRs. An in-house algorithm was used to detect bubbles and compute various characteristics. The results show that the novel nozzle generated smaller bubbles at higher detachment frequency compared to the standard nozzle at different GLRs. It is observed that the bubbles generated from the novel nozzle were 30% smaller in size, at a detachment frequency, 2-3 times higher than that for the standard nozzle, at low liquid velocities. The results also indicate that the diameter and the detachment frequency of the bubbles generated from the novel nozzle are almost independent of the liquid velocity, which implies that the nozzle maintains small bubble size at a high detachment rate over a range of liquid flow rates. While for the standard nozzle, the bubble size increases and the detachment frequency decreases with a decrease in the liquid flow rate. For a given range of GLRs, the size and detachment frequency of the generated bubbles were comparable for all configurations and orientations of the novel nozzle. An in-depth investigation of the underlying bubble formation process in the novel nozzle in a liquid cross-flow was conducted in a glass nozzle which provide an optical access into the novel

nozzle. It was found that the rebound of the bubble from a side hole under the influence of liquid drag force and hydrostatic pressure plays a key role in the early bubble detachment. The results demonstrated that the novel nozzle design in the liquid cross-flow performs better than the standard nozzle especially at low GLRs.

The internal and external two-phase flow in an effervescent atomizer was experimentally investigated in Chapters 3 and 4 using a high-speed imaging technique. An effervescent atomizer was designed and built with full optical access to facilitate internal two-phase flow imaging. The effect of various atomizer internal geometries and bubble breakers were studied over a range of GLRs in Chapter 3. An in-house algorithm was used to compute various characteristics of the bubbles inside the mixing zone and the spray droplets outside the atomizer. An increase in the GLR was found to result in the transition of the internal two-phase flow from bubbly to slug flow and then to annular flow. Furthermore, an increase in the GLR caused a reduction in the spray droplet size and an increase in the normalized droplet velocity, for all cases.

Distance between aeration holes, aerator tube end-shape and mixing zone length were found to have an impact on the internal and external two-phase flow in an effervescent atomizer. The in-depth investigation of the underlying two-phase flow behavior inside the different zones of the effervescent atomizer and the impact of that on the spray quality were also provided. In the aeration zone, the bubble formation from the aeration holes and their advection in the annular region of the atomizer were investigated. The downward movement of the bubbles was found to be influenced by several force components which are (i) liquid pressure drag force from the top, (ii) liquid skin friction drag from the sides, (iii) skin friction drag due to the aerator exterior surface and the atomizer body inner surface, and (iv) buoyancy force. Any changes in these force components were also found to affect the local advection velocity of the bubbles. Any changes in the distance between the aeration holes also led to a change in the bubble-bubble interaction, which may further cause bubbles collision and coalescence. The detailed investigation of the two-phase flow behavior inside the aeration zone along with the mixing zone depicted the fundamental bubble formation process and its advection into

the mixing zone with a better insight. The results showed that the longer distance between the aeration holes results in larger bubbles at a given GLR.

The aerator tube with a flat base was found to generate a flow separation leading to the formation of a large separation bubble in the wake region. It was observed that the bubbles generated in the aeration zone interact with the separation bubble. Such interaction could take various forms, which are (i) causing the separation bubble to meander, (ii) coalescence of smaller bubbles with the separation bubble, (iii) collision of the smaller bubbles with the separation bubble without coalescence (iv) coalescence of smaller bubbles and the interaction of coalesced bubble with the separation bubble, and (v) deformation and breakup of the separation bubble. These interactions contribute to the non-uniformity of the bubble size as well as the flow unsteadiness in the mixing zone. However, when the conical insert was attached to the bottom face of the aerator tube, it streamlined the flow and hence the wake formation was suppressed, thus, no separation bubble was formed. This resulted in more bubble size uniformity and flow steadiness. The impact of conical base was significant on the internal flow and the atomization was improved when the internal two-phase flow comprised of the bubbly flow. The overall mean diameter of bubbles for the conical base case was 21% smaller than the mean bubble diameter for the standard flat base case. At low GLR, the conical base aerator tube resulted in smaller droplets at higher velocity.

The length of mixing zone was also found to have an impact on the effervescent atomization. The effect of mixing zone length on the two-phase flow behavior inside mixing zone also showed that the longer mixing zones increase the chances of bubbles coalescence, which form large bubbles. Furthermore, it was observed that due to the randomness of the coalescence occurrence, the long mixing zones contribute to the non-uniformity in the bubble size. The results also showed that the shorter mixing zone length generates more uniform and smaller bubbles. Hence, shorter mixing zone could generate steady spray at GLRs higher than that for the longer mixing zones. At low GLRs, the overall bubble size in 32 mm long mixing zone was 32% smaller than that in the 75 mm mixing zone. It was observed that when the internal flow is in the bubbly regime, small size droplets are produced by the shorter mixing zone at low GLRs. The normalized

droplet velocity was also found to be slightly lower for the longest mixing zone. An improvement of the spray steadiness and the atomization process were observed with a conical base aerator tube and a shorter mixing zone.

The effect of bubble breaker on the bubble size was investigated in Chapter 4. The detailed investigation of the effect of new bubble breakers inside the mixing zone on the internal two-phase flow characteristics illustrated the significant impact of the bubble breaker on the bubble size reduction. The sudden contraction of the flow at the bubble breaker was found to cause a local increase in the velocity and also velocity gradients. This shear flow of the liquid is likely the dominant mechanism for the upstream bubble breakup. The presence of the conical base of the aerator tube also found to play a role in streamlining the flow and causing the bubble stretching which further supports the bubble breakdown. The sudden contraction induced a liquid velocity component in the horizontal direction immediately above the bubble breaker. It was observed that as the elongated bubbles try to negotiate sudden contraction, they further stretched and formed a “neck” at the bubble breaker entrance. This neck often breaks due to the sharp edge at the entrance or due to the horizontal liquid velocity component. Hence, the bubbles normally started to break as they enter the breaker. The results also showed that the small-size bubbles entered the insert without breaking could break inside the insert due to the interaction of shear and surface tension forces and/or presence of shedded turbulent vortices inside the hole.

The results showed the impact of the breaker-hole diameter and the number of breaker holes on the internal and external two-phase flows. It was observed that the bubble breaker reduces the bubble size by 15% to 67% for various configurations and GLRs. The size of the bubble breaker hole and the number of holes were also found to have an impact on the internal and external two-phase flow characteristics. By decreasing the breaker-hole diameter, more uniform and smaller bubbles were generated at different GLRs. The results also indicated that the atomizer with the bubble breaker was able to produce smaller droplet size compared to the case without a bubble breaker. Among all the single-hole bubble breakers, the smallest breaker-hole was found to have more prominent effect, where on average, the droplet sizes are 7% smaller than that for the

case without breaker for the given GLR range. The results showed that with an increase in the number of breaker holes, the droplet size decreases monotonically. The multi-hole breakers were found to provide a relatively finer spray (8% smaller droplets than that in the case without the bubble breaker) with higher velocity. A higher spray steadiness during atomization was observed for the atomizer with the bubble breaker.

## 5.2 Recommendations for future work

The present research investigated the effect of the novel nozzle design subjected to liquid cross-flow to gain a better insight of the internal two-phase flow in an effervescent atomizer. The novel nozzle in the future could potentially be used in the effervescent atomizer or other industrial applications. It is highly recommended to design an effervescent atomizer using the novel nozzles as an aeration system inside the mixing chamber. One of the measurement techniques is PIV, which can be used to investigate the bubble formation from the novel nozzle made of glass. This provides a better understanding of the effect of surrounded liquid behavior on the bubble formation and detachment. The results showed that liquid cross-flow reduces the rate of bubbles coalescence, however with an increase in the gas flow rate the chance of bubbles coalescence increases. PIV measurement is highly recommended to improve the knowledge of bubbles coalescence phenomenon in a liquid cross-flow and investigated the impact of liquid cross-flow on the bubbles coalescence.

Another aspect is the bubble breaker design. The results showed a clear impact of the bubble breaker inside the mixing zone upstream of the exit orifice on the bubble size reduction and spray droplet size. An experimental study using various lengths of bubble breaker at different locations inside the mixing chamber would provide a detailed investigation of the effect of breaker on the size of fragmented bubble downstream of the bubble breaker. Moreover, the spray characteristics were measured at the center of the spray, while the measurement of the spray droplets size at different radial distances from the center of the spray under the same condition is recommended

### 5.3 Contributions

In the present research, for the first time, the detailed investigation of the dynamic of two-phase flow in the novel nozzle subjected to the liquid cross-flow was studied. The underlying bubble formation mechanism inside the glass novel nozzle was also investigated for the first time. Utilization of the novel nozzle in the effervescent atomizer and other related applications may result in a less energy consumption, due to the nature of the novel nozzle to generate smaller bubbles at higher detachment frequency.

The present results provide the detailed investigation of the two-phase flow inside and outside the effervescent atomizer. Detailed characterization of the effect of mixing zone length and aerator tube base configuration on the nature of the two-phase flow inside the mixing zone and hence the spray quality was studied for the first time. The effect of a new bubble breaker and its configurations inside the atomizer was investigated and found to improve the effervescent atomization. For the first time in the present study, the mechanism of bubble fragmentation inside the new bubble breaker was investigated.
