Binding of Salivary Proteins to Orthodontic Brackets

ABSTRACT:

Objectives: The aim of this study was to investigate the effect of different orthodontic materials on the formation of the protein pellicle on the bracket surface.

Materials and Methods: We used X-ray Photoelectron Spectroscopy (XPS) to analyze the atomic composition of orthodontic metallic and ceramic brackets. Following XPS, the brackets were immersed in human whole saliva supernatant for 2-hour incubation at 37°C. Hydroxyapatite (HA) discs were used as control. Acquired pellicle was harvested with sonication for each group, and liquid chromatography electrospray ionisation mass spectrometry was used for protein identification.

Results: Differences reported by XPS and mass spectrometry were noted among the tested groups. Most of the proteins present on the acquired pellicle were identified specifically to each group, indicating little overlap in the acquired pellicle proteins; 84% of proteins present on the HA discs were unique to this group, 74% were unique to ceramic brackets and 79% were unique to metallic brackets. Despite the fact that most proteins were unique to each bracket material, proteins related to antimicrobial, lubrication and remineralization biological functions were present in all groups. However, proteins associated with inflammatory processes and biofilm formation were found only on ceramic brackets.

Conclusions: The results demonstrate that the protein pellicle formed on the bracket surface is dependent on the molecular composition of the bracket. Therefore, our findings suggest that modulation of the bracket pellicle via alteration of bracket surface is a possibility.

Key words: orthodontic brackets, acquired enamel pellicle (AEP), Acquired bracket pellicle (ABP), X-ray Photoelectron Spectroscopy (XPS), Mass Spectrometry, LC-ESI-MS/MS, Protein Identification, Dental caries, white spot lesions (WSL)

Co-Authorship:

The completion of this thesis was possible due to the contribution of several individuals. It would not have been possible without their valued time and efforts, which was greatly appreciated.

Maria Pia Canales: DMD,
Master of Clinical Dentistry Candidate, Graduate
Orthodontics

Contribution: Manipulation of all laboratory experiment, data collection
and analysis of all experiments, author manuscript

Walter Siqueira: DDS, PhD
Thesis supervisor
Associate Professor, Dentistry
Associate Professor, Biochemistry

Contribution: Study design, data analysis for XPS and mass spectrometry,
reviewed manuscript

Karla Crosara: DDS

Contribution: Study design, data collection and analysis for XPS and
mass spectrometry, reviewed manuscript

Camila Martins: DDS

Contribution: Manipulation of all laboratory experiment, data collection
and analysis of all experiments and reviewed manuscript

Acknowledgement:

I would like to express my sincere gratitude to all colleagues, friends and teachers that have contributed to the accomplishment of this project.

I would first like to thank my supervisor, Dr. Walter Siqueira, for taking on an amateur research student like myself. Your guidance and patience from day one have been invaluable in allowing me to progress through this project. Thank you for your time, knowledge, effort and especially your passion throughout this journey.

I am very grateful that I have been helped by Karla Crosara since the beginning of this project. You have been a key player in the smooth progression of this thesis and I have truly enjoyed working with you. Thank you for all your knowledge, expertise, tips and patience. I could not have asked for a better research co-supervisor. Good luck on your PhD degree.

Thank you to my friend and colleague Camila Martins; your hard work in every step of this project was greatly appreciated. You were always prepared to help me and made this project enjoyable. I certainly had a great time with you in the lab!

A special thanks to Siqueira Lab members who were always ready to help me with laboratory techniques. I would also like to thank the saliva donors who contributed to this project; thank you for your contributions.

Thank you to my friend Dr. Jonathan Albilia for your many corrections on my franco-spanish misspelled words. Thank you for your time and patience.

I would also like to thank American Orthodontics for their generous contribution, allowing

us to utilize their orthodontic brackets for our research.

I would like to extend the most sincere gratitude to my department chair and clinical professor Dr. Antonios Mamandras. You have always been a “father” for all of us. Thank you to my clinical director Dr. Ali Tassi for your dedication to the clinic and to its residents. I would also like to thank all our numerous clinical instructors for your teachings and commitment to helping all of us to become better every day.

I would also like to thank the members of my examining committee: Dr. Jeff Dixon, Dr. Andrew Leask and Dr. Sahza Hatibovic-Kofman.

Last but not least, I would like to thank my parents, Beatriz and Jorge, and the rest of my family Patricio, Rudy, Pablo, Nicole, Analie, Jessica and Isaac for their continuous love and support.

CHAPTER 1: Orthodontic and Pellicle

1.1 Introduction

A constant concern in the orthodontic clinic is the high prevalence of active carious lesions in patients undergoing treatment. In fact, it has been noted that 30 to 70% of patients experience active caries lesions during orthodontic treatment (1,2). A Previous study (3) described an alarming increase of 2.5 times in active non-cavitated carious lesions in orthodontic patients compared with the normal population. It is also reported that orthodontic appliances decrease the saliva's buffering capacity and decrease the quantity of salivary α -amylase after they are in place for 3 and 6 months, suggesting that the properties of saliva of orthodontic patients are subject to changes (3). This may have a repercussion on the rate of active caries lesions, as the severity of these lesions can progress from active white spots to frank cavitation of the enamel.

It is well known that the level of bacterial growth on the surface of the orthodontic brackets is variable depending on the material of the bracket (4-6). Furthermore, composite brackets have been reported to attract bacterial colonization at a rate higher than any other bracket (7). Several studies have focused on the initial bacterial binding to different orthodontic brackets (5,8,9) trying to understand which material is more prone to cariogenic bacterial adhesion. However, there is little information in the literature about the protein pellicle that initially adheres to the brackets.

In the oral cavity, it is recognized that specific proteins/peptides have a greater affinity for enamel than others, based in part on their surface charges (10). The acquired enamel pellicle (AEP) is a thin protein layer formed on the tooth surface that plays a key role in the maintenance of oral health by regulating processes such as lubrication, demineralization, and remineralization (11). The AEP

also influences the composition of the early microbial flora adhering to tooth surfaces (11). Nevertheless, salivary pellicles are not limited to the surface of the tooth. These are also present on the oral mucosa (12), dental appliances like orthodontic brackets (8), and even restorations and titanium implants (13).

In a previous investigation (14), Liquid Chromatography – ElectroSpray Ionization tandem Mass Spectrometry (LC-ESI-MS/MS) was used to investigate the protein composition of the *in vivo* AEP. This study disclosed that this natural film contains at least 130 different proteins. Through proteomic analysis, it is possible to discover the salivary components of the AEP. It will be interesting to use this advanced technology to understand protein pellicles specific to orthodontic brackets, which will provide an awareness and understanding of the future biofilm formation.

The mechanism by which proteins adhere to surfaces is heavily determined by physico-chemical properties of the material. Therefore, analyzing the nanostructure of orthodontic brackets, for example, may provide important information regarding the reasons why specific proteins may selectively adhere to orthodontic fixed appliances. X-ray photoelectron spectrometry (XPS) is a powerful tool that gives information about elemental distributions, coating structure and surface functionality of materials (15). XPS can detect all elements (except hydrogen and helium) (10) and can provide information on particle sizes in the 1-20 nm scale (15). XPS probes the surface of the sample to a depth of 5-10 nanometers (10) and provides a complete profile about the composition of a sample near the surface area, which is the region directly in contact with the oral cavity.

Since orthodontic treatment lasts for an average of two years, the composition of the protein pellicle on the bracket surface, and the consequent biofilm formation, will have a selective impact on the abundance of specific oral microorganisms.

The objectives of this study were:

1. to investigate the molecular composition of two types of orthodontic brackets (metallic and ceramic);
2. to characterize the composition of the acquired protein pellicle formed on the surface of the different orthodontic brackets; and
3. to investigate the correlation between the molecular composition of the bracket surface and the proteins identified in the acquired bracket pellicle.

Our findings will attempt to give more information on the uncharacterized acquired bracket pellicle for a future possible way to modulate it to reduce oral biofilm formation on the surface of orthodontic brackets.

1.2 Literature Review:

1.2.1 Orthodontic treatment and Dental Caries:

White spot lesions are the precursor of dental cavitation and they are a constant concern for clinicians and orthodontic patients. A white spot lesion is the first clinical sign of active dental caries, and thus allow for early diagnosis (3). Organic acids produced mainly by cariogenic streptococci can be responsible for this demineralization (16). Furthermore, tooth demineralization has been reported to be the most common complication of fixed orthodontic treatment, present in 50% of orthodontic patients (17). In only four weeks, this unaesthetic lesion can appear on the surface of the enamel (18). Orthodontic patients are very prone to develop these lesions because of the difficulty in maintaining excellent oral hygiene. Most orthodontic patients also wear orthodontic adjuvant devices (ex: power chains, open coils, closed coils) that can cause a significant increase in plaque retention, possibly compromising their oral health. In addition, it has been suggested that metallic orthodontic brackets decrease the salivary pH (19) and increase colonization by *Streptococcus mutans* (20).

Several studies have focused on the initial bacterial binding to different orthodontic brackets (5,8,9) trying to understand which material is more prone to cariogenic bacterial adhesion. Effectively, the composition of the initial bacterial attachment differs depending on the surface material of the bracket (6,21). It has been reported that qualitative and quantitative variations were observed on the biofilm after only 30 to 60 mins of intra-oral exposure of different brackets (21). Furthermore, it also has been demonstrated that the affinity for *Streptococcus mutans* is significantly lower on metallic brackets compared with the other materials (22). However, little

information is available on the adhesion of various proteins to different orthodontic brackets, which may impact biofilm formation.

1.2.2 Saliva characteristics:

1.2.2.1 Saliva definition and composition:

Saliva is a clear, slightly acidic (pH 6 to 7) and mucoserous exocrine secretion. It contains 99% water, electrolytes (sodium, potassium, calcium, chloride, magnesium, bicarbonate, phosphate), immunoglobulins, mucins and other proteins. Glucose and nitrogenous products (urea and ammonia) are also present in the saliva (23,24).

1.2.2.2 Whole saliva:

Whole saliva (or total) is a complex fluid mixture derived from major and minor salivary glands, crevicular fluid, oral mucosa transudate, mucous of the nasal cavity and pharynx, non-adherent oral bacteria, food remainders, desquamated epithelial cells and blood cells. Traces of medications or chemical products found in the systemic circulation can also be detected (23). Whole saliva include stimulated and unstimulated saliva.

There are different methods available for collecting whole saliva. Common methods include spitting, suction, and swab (absorbent), Fejerskov & Kidd (25) reported that salivary composition varies according to the nature of the stimulus (gustatory or mechanical) and on the duration. A study of unstimulated, chewing-stimulated, and pure parotid saliva has revealed differences in metabolite profiles between the three types of saliva (26). These results reinforce the importance

of using the same saliva collection method when comparing protein levels within a study or among studies.

1.2.2.3 Salivary glands:

The major salivary glands include paired parotid, submandibular and sublingual glands. Thousands of proteins could be identified in the major salivary glands compare to only 56 proteins in the minor salivary glands (27). Minor glands are multiple small glands found around the entire oral cavity, except for the gingivae, anterior hard palate and tongue dorsum (28). They contribute 10% of the total volume of human saliva (29). They have been reported to have a relative enrichment of mucins (MUC5B and MUC7) and immunoglobulins (8 different types) (27). Siqueira reported that there is a unique protein composition from minor salivary gland saliva (27). Cystatins, large salivary-proline-rich protein family, histatins and 12 new salivary proteins have been noted (27).

1.2.2.4 Salivary flow:

At rest, there is a small and continuous salivary flow of 0.3-0.5 mL/min (28). During that unstimulated state, the percentage contributions of the salivary glands are 20% from the parotids and 65% from submandibular (24). Furthermore, the unstimulated flow rate from all the minor salivary glands in the mouth has been reported to 7–8% of the unstimulated flow rate of whole saliva (29).

Stimulated saliva is produced by a mechanical, gustatory, olfactory or pharmacological stimulus. It represents 80-90% of daily salivary production (23). The percentage contribution of the parotid salivary glands drastically change to more than 50% when saliva is stimulated (30).

The saliva rate and the concentration level of salivary components vary according to the time of the day (31). Circadian low flow occurs during sleep, and peaks during stimulation periods (24). The unstimulated flow rate for parotid, submandibular and whole saliva attain a peak value around 15h30 and fall virtually to zero during sleep (32). This has a big implication in preventive dentistry. The age of the subject can also be a factor on protein concentration of the unstimulated saliva (33). For stimulated saliva, protein concentration can change depending on the flow rate, the nature of the stimulus, the duration of the stimulation, the circadian rhythm and the effects of previous exercise (32,34,35).

The saliva is first formed inside the acini; this saliva is isotonic with respect to plasma. It becomes hypotonic after it runs through the network of ducts (36). There is a low level of glucose, sodium, chloride and urea in the hypotonic saliva that allows the dissolution of substances and allows the gustatory buds to perceive different flavors. One important protein for the growth and maturation of the gustatory buds is gustatin (24).

Both sympathetic and parasympathetic nerve fibers innervate the salivary glands. When sympathetic innervation takes control, the salivary secretions contain more proteins (mucous). However, when the parasympathetic system dominates, the saliva will be more serous (30).

1.2.2.5 Type of secretion:

The saliva is first secreted in the acinar cells, these cells determine the type of secretion produced from the different salivary glands. There are three types of secretions: serous, mucous or mixed. The principal producer of serous secretions are the parotid glands and mucous secretions come

from the minor glands. Mixed secretions (mucous and serous) are in general produced by the sublingual and submandibular glands (24).

Parotid saliva contains amylase, proline-rich proteins and agglutinins. It also contains some amount of cystatins, lysozymes and extraparotid glycoproteins (24). Furthermore, parotid glands are by far the main source of amylase in whole saliva, but doesn't secrete mucins (34). In consequence, the percentage contribution of parotid to whole saliva will influence the relative proteins proportions. Sublingual saliva consists of a high concentration of both types of mucins (MUC5B and MUC7) and high levels of lysozymes (24). Furthermore, palatine secretions will have important concentration of MUC5B mucins and relatively high amylase concentrations (37).

1.2.2.6 Role of saliva:

Salivary function can be separated into 5 major groups for maintaining oral health and creating an appropriate ecologic balance. The five major roles are: (1) lubrication and protection, (2) buffering action and clearance, (3) maintenance of tooth integrity, (4) antibacterial activity, and (5) taste and digestion (38,39).

Lubrication and protection of the oral tissues against irritating agents is possible due to mucins (24). Macromolecules (proteins and mucins) will also serve to cleanse, aggregate and attach oral microorganism. This will have an impact on dental plaque metabolism (24).

The importance of buffering capacity of the saliva will prevent colonization by potential pathogenic microorganism. Effectively, bicarbonate, phosphates and urea will modulate the pH and the buffering capacity of saliva (24). Bicarbonate is the most important buffering system because it diffuses into plaque and neutralize acids (24). Furthermore, peptides rich in histidine

also are direct buffers after diffusion into the plaque (40). When salivary flow increases, the concentrations of total protein, sodium, calcium, chloride, bicarbonate and the pH will increase to different levels, but the concentration of inorganic phosphate and magnesium will decrease (24).

Enamel demineralization prevention by neutralizing the acids, coming from acidogenic microorganism, is possible due to calcium, phosphate, fluoride and proteins (11). The mechanisms by which AEP proteins (histatins, statherin and mucins) contribute to the enamel demineralization protection maybe be related on retarding enamel loss during acid challenges (11).

The antibacterial function comes from the immunoglobulins (IgA, IgG and IgM), proteins and enzymes (lactoferrin, lysozymes and peroxidase) present in the saliva. IgA, however, is the largest immunologic component of saliva (24).

1.2.2.7 Proteins:

Salivary proteins are multifunctional, they can be functionally redundant, and they can act both for and against the host (41). Statherins, histatins, cystatins, and proline-rich proteins are proteins present in the protective pellicle, acquired enamel pellicle (AEP). They bind to hydroxyapatite and help control the crystalline growth of the enamel. They limit the dissolution of the minerals and allow the penetration of minerals into the enamel (24).

Proteins such as glycoproteins, statherins, agglutinins, histatins, and proline-rich proteins can aggregate bacteria to reduce their ability to adhere to hard/soft tissue surfaces. This in turn will control bacterial, fungal, and viral colonization (24).

Histatins:

Negative salivary proteins like histatin 1 have been reported to have a strong affinity to hydroxyapatite (HA) discs and they are considered pellicle precursors (10). Research has shown that histatins 1 have a buffering function, as well as strong antifungal and antibacterial activities (42). They can also modulate mineral formation and provide a protection against acid injury (43).

Statherin:

Statherin is a low molecular weight protein and is negatively charged. It can inhibit primary and secondary calcium phosphate precipitation (10). This will inevitably affect the control of dental calculus formation and remineralization of early dental caries (10). Statherin also facilitates the binding of *Actinomyces viscosus* (45) and *Fusobacterium nucleatum* (46), determinant initial microbial colonizers of tooth surface.

Cystatins:

Human saliva contains multiple forms of cystatins; they all belong to family 2 of the cystatin superfamily (47). Some cystatins can have a neutral pI (cystatin SN) and others an acidic pI (cystatin SA) (47). Cystatins are considered as one of the most abundant proteins in the AEP on in situ studies (11). It demonstrates an affinity to mineral surfaces and can also inhibit calcium phosphate precipitation (48). Cystatins play an important role in maintaining the integrity of teeth (48).

Proline-Rich-Proteins (PRP) :

Proline-rich proteins are major components of parotid and submandibular human saliva. They can be divided into three groups; glycosylated, basic and acidic proline-rich proteins. The unique structure of the acidic proline-rich proteins doesn't belong to any known protein family. Furthermore, this protein has a role on the inhibition of hydroxyapatite formation. (49).

Mucins:

Mucins are proteins with a high carbohydrate content. MUC5B and MUC7 are the major members of the salivary mucin family (27). They are synthesized and secreted by submandibular, sublingual and minor salivary glands (50). In the oral cavity, they play an integral role in non-immune protection (51). They are responsible for lubrication, and protection against desiccation and environmental insult. They also have an important antimicrobial effect against potential pathogens (51). Effectively, they can modulate the adhesion of microorganisms to the oral tissue surfaces, and in consequence they contribute to the control of bacterial and fungal colonisation (51). Furthermore, mucins form complexes with other salivary proteins such as amylase, statherin, histatin and PRPs (52). These complexes may protect the proteins from enzymatic degradation or may enhance their function (27). They also facilitate daily functions such as mastication, speech and deglutition through their lubrication effect (24).

MUC5B is a high molecular weight gel forming mucin, it plays a role on the viscoelasticity of saliva (53). It has a high affinity for hydroxyapatite (54) and is a component of the acquired enamel pellicle (55). MUC7 on the other hand, is a low molecular weight monomeric mucin and has demonstrated affinity for cementum (56). It also binds to bacteria such oral Streptococci (13).

1.2.3 Acquired Enamel Pellicle:

1.3.3.1 Definitions

The acquired enamel pellicle (AEP) (10) is a thin film acquired on the surface of the teeth when exposed to the oral environment. This thin protein film can range from 0.1-1.0 μm in thickness. It is formed by a selective adsorption of many salivary proteins, but carbohydrates and lipids are also present. This protein film is involved in the demineralization-rem mineralization process. Because of its ideal location (between the enamel and biofilm), it will act as a natural diffusion barrier (10).

1.3.3.2 Proteomic Analysis

The molecular structure of the AEP has been difficult to assess, because of the very low quantity of in vivo formed pellicle that can be harvested from the tooth surface (57). It has been estimated that the amount of AEP that can be collected per tooth surface is approximately 0.5-1 μg (58). This will prevent the characterization of this protein film with classical biochemical technologies. The use of hydroxyapatite discs has been used to gain insights into the AEP (14). Therefore, in vitro and in situ studies have provided information on the affinity of salivary proteins with hydroxyapatite surfaces.

By using proteomics technologies (59), a study demonstrated that at least 200 proteins spots were detectable in AEP in a 2-D gel electrophoretogram. But 2-D gels are limited by the dependence on protein separation, the visualization of proteins in the gel, and the labor-intensive processing of excised proteins spots. Mass spectrometric analysis (LC ESI MS/MS), in another hand, can generate a protein profile and sequence information. This allows a direct analysis of extremely

complex biological samples (14) and helps to characterize the peptides down to the femtomole level (14).

One of the persistent challenges in saliva proteomics is the collection and the storing of saliva under conditions that maintain protein structure. Because we need minimal proteolysis, deglycosylation and dephosphorylation prior to proteomic analysis (34), is important to keep the samples on ice during saliva collection and to store the samples at -80°C (34).

Furthermore, because protein concentrations change depending on different factors (60), standardization of collection conditions is crucial for achieving reliable identification of salivary proteins (34).

1.3.3.3 Composition and Function of AEP

AEP has multiple functions such as neutralizing acid production by oral bacteria, acting as a lubrication film, protecting the teeth from abrasive forces (14). Because AEP can dictate the composition of initial microbial tooth colonizers, the AEP can ultimately modulate the oral biofilm and the mature plaque (61) and can have an impact on dental caries formation (14).

Previous research reported a total of 130 different proteins/peptides in the AEP (14). These proteins comprise members of the histatin, statherin, and acidic proline-rich protein (PRP) family (14). Multiple in vitro studies report that histatins, statherins, and acidic PRPs have been shown to be among the first proteins that adsorb on the hydroxyapatite surface (45,62).

Past research (14), has also identified the origin of the proteins. They noted a low value of 14.4% of all proteins derivate from exocrine salivary secretions, 85.6% originated from non-exocrine

contributors to whole saliva (comprising cells (67.8%) and serum (17.8%)) (14). They concluded that it is possible that more proteins will be identified as salivary glandular secretions with future studies (14).

Four main groups forming the AEP have been identified in past research (14), when proteins are grouped according to their chemical properties. (Figure 1).

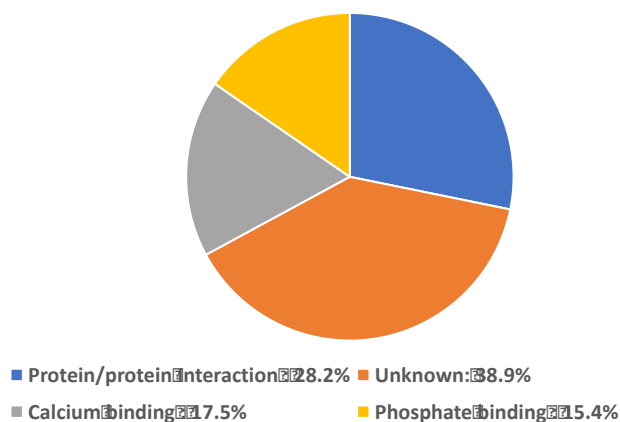

Figure 1: Classification of AEP proteins by their chemical properties. (14)

The first group is proteins that can bind calcium ions (17.5% of identified AEP proteins). They include S100 calcium binding protein family and members of the annexin family. They are considered pellicle precursor proteins due to their affinity to the calcium ions on the enamel surface. The other group (15.4%) are proteins that have a high tendency to bind to phosphate ions, such as elongation factor 2 and myosin-9, which are also in the primary protein layer because of their phosphate affinity. The third group (28.2%) identified in the literature (14) are proteins that have an interaction with other protein, such as MUC5B, which are suspected to be involved in the formation of the successive protein layers.

The other way that AEP proteins have been categorized are according to their biological function. Some proteins have remineralization capacities such as calgranulin and annexin families. Other proteins like cystatins (S, SA, A, B, D), lysozyme, lactotransferrin, myeloperoxidase, calgranulin A, and calgranulin B are essential for oral host defense against pathogens. These proteins are involved in the acquired immune response (11.3%) or antimicrobial activity (8.3%) (14) (Figure 2).

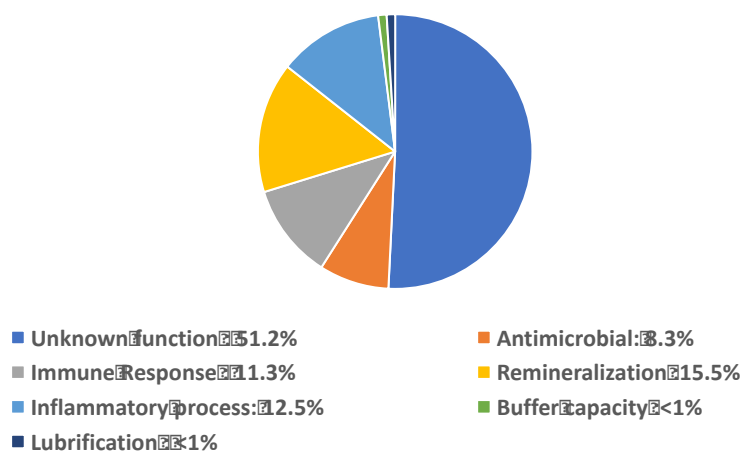

Figure 2. Classification of AEP proteins by their biological function. (14)

It has been noted that the level of gingival inflammatory disease can also have an impact on the AEP, therefore albumin, alpha-1-antitrypsin, cathepsin G, complement C3, and myeloperoxidase have been identified in the AEP components. These biomarkers for periodontal disease constitute 13% of the total number of AEP proteins (14).

1.3.3.4 Salivary pellicles on orthodontic brackets:

Salivary pellicles are not limited to the surface of the tooth. These are also present on the oral mucosa (12), dental appliances like orthodontic brackets (8), and even restorations and titanium implants (13).

Bacterial adhesion to the surface of orthodontic brackets involve a specific lectin-like reaction (63), electrostatic interactions and Van der Waals forces (64). Initial attachment of bacteria is an important factor that influences further colonization. The composition of the initial bacterial attachment differs depending on the surface material of the orthodontic bracket (6,21). Recent studies have found that composite brackets exhibit greater biofilm formation when compared to metallic and ceramic brackets (7). Fournier et al. (22) also found that the affinity for *Streptococcus mutans* was significantly lower on metallic brackets compared with the other materials.

Amylase, secretory IgA, acidic proline-rich proteins, and cystatins adhere to all kinds of brackets. However, when an electrophoresis approach was used, the differences in the gel profiles depending on the bracket material was evident, showing the selective nature of salivary protein binding (6). The largest differences observe was on the plastic brackets where acidic PRPs were more evident (6). Besides, Lee (8) reported that the pellicle components on metal brackets, were almost the same as those on the elastomeric ligature ring, with the exception that MG1 was not present on the ligature ring. Also, the degree of adhesion of cariogenic streptococci was significantly higher for bonding adhesives than for bracket materials (65).

The main factor for adhesion of Streptococci to orthodontic brackets are the bracket type, the incubation time and the saliva coating. Past studies also reported that differences can be found between the protein adsorption on the manufactured metal bracket and the raw metal material, due to surfaces properties that can change with manufacturing (8).

Besides, *S. gordonii* has been found to adhere to orthodontic brackets by a factor of 10 times more than *S. mutans*, which suggests that *S. gordonii* can be the initial colonizer on the orthodontic brackets (6).

Higher critical surface tension, higher wettability and higher roughness of the material are variables that will have an impact on promoting biofilm adhesion (21). Surface free energy have been reported to be higher on stainless steel (SS) orthodontic brackets than ceramic brackets (21). According to that finding, bacterial adhesion should be greater on SS brackets. However, Lim et al (65) report less cariogenic streptococci adhesion on SS brackets. They concluded that a low association between surface energy and bacterial adhesion is because of others factors like surface roughness, surface charge and hydrophobicity.

Knowing that each biomaterial has unique chemical properties and surface energies, we suspect that proteins will bind differently depending on the properties of the orthodontic brackets.

1.2.4 Composition of Orthodontic Brackets:

1.2.4.1 *Metallic orthodontic brackets:*

There are different materials used for manufacturing orthodontic brackets including metals, plastics and ceramics. Stainless steel brackets are commonly used (66) because they have appropriate physical properties, good corrosion resistance and are affordable. Stainless steel is available as type 304, 316 and 17-4 PH SS. Most orthodontic (66) brackets are made from AISI type 304L SS, which contains 18-20% chromium and 8-10% nickel. They also have a small amount of manganese and silicon, plus a low carbon content (0.03% and less). Some manufacturers use type 316L SS, with higher nickel content, 2-3 % molybdenum, and a lower carbon content for better welding characteristics (66). Table 1 represent common elements documented by an orthodontic company for the composition of their SS orthodontic brackets.

Furthermore, the base and the wings of the brackets are mostly austenitic-type stainless steel alloys (303L, 304L, 316L, PH-14-4) and Titanium can also been found (67). The mesh is attached to the base by using brazing methods for stainless steel orthodontic brackets. Brazing fillers alloys need to be used between the bracket base and wing interface. Most SS alloys can be brazed with several different filler metal families, including: Silver, Nickel, Copper, and Gold (67).

Table 1: Composition of SS orthodontic brackets (reported by AO company)

Components	% by Weight
Silicon, Si	0 to 1.0
Manganese, Mn	0 to 2.0
Chromium, Cr	13 to 23

Nickel, Ni	3 to 14
Molybdenum, Mo	0.5 to 3
Copper, Cu	1.25 to 5
Niobium, Nb	0.15 to 0.45
Iron, Fe	50-80

Others elements may be present such as Carbon, Sulfur and Phosphorus. These are not hazardous or below 0.1% by weight.

The metallic brackets are fabricated by three main methods: casting, metal injection molding (MIM), and milling (68). The most recent technique is MIM, which is less expensive compared to the two others techniques. However, the best precision of bracket slot size is accomplished by milling the slot of a cast bracket (72).

1.2.4.2 Ceramic Orthodontic brackets

Aesthetics has become an important aspect when patients choose to have braces. Ceramic brackets are often used, they are made of high-purity aluminum oxide, and can be available in two forms; polycrystalline and monocrystalline. The monocrystalline brackets have the advantage of containing fewer impurities and having an excellent optical clarity.

Composition of ceramic brackets has been reported to be 100% Aluminum Oxide. A previous study (70) showed a variety of structural, compositional, and topographical characteristics when they analyzed ceramic brackets from different companies. They found the presence of single-crystal aluminum oxide (Al_2O_3), polycrystalline Al_2O_3 , or Al_2O_3 and silicon oxide (SiO_2). They

also reported different brackets with rough or smooth bases. The rough areas on the bases consisted of sharp crystals or spherical glass particles.

1.2.5 X-Ray Photoelectron Spectroscopy (XPS)

XPS is a powerful tool for understanding the nature of many different types of surfaces, it can provide abundant information about elemental distribution, thickness, and surface functionality (15). XPS can detect all elements (except hydrogen and helium) (10) and can provide information on particle sizes on the 1-20 nm scale (15). XPS probes the surface of the sample to a depth of 5-10 nanometers (10). In other words, because the electron link to the XPS only travel a certain specific distance, it can only provide a complete information about the composition of a sample near a surface region (15).

Because electrons, can travel a short distance within a material without losing energy, we can measure the surface composition of a material, this is also possible because there is a multitude of past research about how nanostructure influences the peak intensities, signal background and the binding energies of photoelectron peaks of nanostructure materials. For example, the instrument can be calibrated to give a binding energy of 83.96 eV for the Au 4f_{7/2} line for metallic gold and the spectrometer dispersion can be adjusted to give a binding energy of 932.62 eV for the Cu 2p_{3/2} line of metallic copper (10). The other elements will be relative to this calibration.

XPS on the surface of the orthodontic bracket is very relevant, because it is providing qualitative information on the elements present at the bracket surface and it is to this surface that proteins and bacteria will adhere. This adherence will potentially cause a biofilm and can initiate caries lesions on the surround areas.

1.2.6 ElectroSpray Ionization tandem Mass Spectrometry (LC-ESI-MS/MS)

Mass spectrometric analysis (LC ESI MS/MS), can generate a protein profile and sequence information and allows characterization of peptides down to the femtomole level (14). This allows a direct analysis of extremely complex biological samples (14).

A research report (28) on phosphoproteome exploration using mass spectrometry was challenging because of the dissociation of phosphate groups during collision induced dissociation fragmentation step, which will hide the location of the phosphorylation sites. One of the solutions reported in the literature is the initiation exploration of the phosphoproteome of saliva using a chemical derivatization of the phospho-serine/ threonine-containing proteins and covalent disulfide-inter-change chromatography to capture and enrich phospho-peptides followed by intensive MS analysis, where the MS/ MS data define the location of the P-Ser and/or P-Thr residues within the amino-acid sequence. That technique allows a better comprehensive study of the phosphocreatine (28,71).

CHAPTER 2

Binding of Salivary Proteins to Orthodontic Brackets

INTRODUCTION

A constant concern in the orthodontic clinic is the high prevalence of active caries lesions in patients undergoing treatment. In fact, it has been noted that 30 to 70% of patients experience active caries lesions during orthodontic treatment (1,2). Since orthodontic treatment lasts for an average of two years, the composition of the protein pellicle on the bracket surface, and the consequent biofilm formation, will have an important impact on the abundance of specific oral microorganisms.

The mechanism by which proteins adhere to surfaces is heavily determined by physico-chemical properties of the material. Therefore, analyzing the nanostructure of orthodontic brackets, for example, may provide important information regarding the reasons why specific proteins may selectively adsorb to orthodontic fixed appliances. X-ray photoelectron spectrometry (XPS) is a powerful tool that gives a multitude of information about elemental distributions and surface functionality of materials (3). XPS can detect all elements (except hydrogen and helium) (4) and can provide information on particle sizes in the 1-20 nm scale (3). XPS probes the surface of the sample to a depth of 5-10 nm (4) and provides a complete profile about the atomic structure of the surface area.

Salivary pellicles are not limited to the surface of the tooth, they are also present on the surface of the oral mucosa (5), on prosthetic restorations (6), and on dental appliances like orthodontic brackets (7). The acquired enamel pellicle (AEP) is a thin protein layer formed on the tooth surface

that plays a key role in the maintenance of oral health by regulating processes such as lubrication, demineralization, and remineralization (8). In previous investigation (9), *Liquid Chromatography – ElectroSpray Ionization tandem Mass Spectrometry* (LC-ESI-MS/MS) was used to investigate the protein composition of the *in vivo* AEP. This study disclosed that this natural film contains at least 130 different proteins. Through proteomic analysis, it is possible to discover the salivary components of the AEP and understand their functions. It will be fruitful to use this advanced technology to understand the protein pellicle specific to orthodontic brackets. This will provide an awareness and understanding of the future biofilm formation.

It is well known that the level of bacterial growth on the surface of the orthodontic brackets is variable depending on the material of the bracket (10-12). Furthermore, composite brackets have been reported to attract bacterial colonization at a rate higher than any other bracket (13). Several studies have focused on the initial bacterial binding of different orthodontic brackets (7,11,14) trying to understand which material is more prone to cariogenic bacterial adhesion. However, there is little information in the literature about the protein pellicle that initially adheres to the brackets and consequently leads to biofilm formation.

The purposes of this study were to investigate the molecular composition of two types of orthodontic brackets (metallic and ceramic) as well as to characterize the composition of the acquired protein pellicle formed on the surface of the different orthodontic brackets.

MATERIALS AND METHODS

X-ray Photoelectron Spectroscopy

X-ray Photoelectron Spectroscopy (XPS) was used to atomically analyze the composition of orthodontic metallic brackets (1.1/2.1 bracket) from American Orthodontics company, ceramic brackets (1.1/2.1 bracket) from the same company and hydroxyapatite discs (5 mm dia x 1.5-1.8 mm thick Himed inc.). Each bracket and disc were cleaned 5 minutes by sonication in 800 μ L distilled water. Immediately after that, one bracket of each group and one discs were incubated for 2 hours at 37°C in 800 μ L MiliQ water. Subsequently, XPS atomic analysis was performed on the incubated and not incubated samples.

XPS was calibrated with the same parameters used before (4). The instrument work function was calibrated to give a binding energy (BE) of 83.96 eV for the Au 4f_{7/2} line for metallic gold and the spectrometer dispersion was adjusted to give a BE of 932.62 eV for the Cu 2p_{3/2} line of metallic copper. The Kratos charge neutralizer system was performed on all specimens. Survey scan analysis were accomplished with an area of 300x700 μ m and a pass energy of 160 eV. Spectra were analyzed using CasaXPS software (version 2.3.14). Every manipulation was repeated three times in order to have triplicates.

Whole saliva collection

Ethics approval was obtained from Research Human Ethics Board of Western University (registration number IRB 00000940) and each subjects of this study received an informed consent. Whole saliva from three healthy subjects (2 females and 1 male) aged from 30-40 years old was collected in the morning between 8h45 and 9h45 under masticatory stimulation using parafilm (25cm²). Subjects were not allowed to eat or drink two hours before saliva collection. Saliva samples were kept on ice to minimize protein degradation during the collection procedure. After collection, all samples were centrifuged at 14,000xg for 20 minutes at 4°C. Following the

centrifugation, whole saliva supernatant (WSS) was separated from the pellet and pooled together for the use in this experiment. The protein concentration of this pooled sample was measured by the bicinchonic acid (BCA) assay (Pierce Chemical, Rockford, IL, USA) with bovine serum albumin used as the standard. Pooled supernatant saliva (μl) was measured and each bracket was incubated in 200 μg of total protein (Appendix 1).

Incubation of Metallic and Ceramic Brackets with Human Saliva

Brackets and HA discs (4 specimens / group) were exposed to 800 μL of distilled water for 2 h at 37°C with gentle agitation (in 24 well culture plate). Subsequently, the pre-treated brackets and HA discs were incubated for 2 h at 37°C with WSS containing 800 μg of total protein. Immediately after protein incubation period, the HA discs and brackets were washed using distilled water to remove any weak binding salivary protein.

Harvesting of in vitro Acquired Bracket Pellicle

Acquired Bracket Pellicle (ABP) and *Acquired Hydroxyapatite Pellicle (AHP)* formed on each of the brackets and disc surface (n=4/ for each group) were harvested by sonication in 300 μL of solution containing 80% acetonitrile, 19.9% water and 0.1% Trifluoroacetic acid (TFA) for 5 min. This procedure was repeated three times. Because the small amount of protein that can be harvest from one group (n=3), eluted pellicle material from the same group (from the triplicates) were pooled and concentrated by a rotary evaporator, in total we pooled 12 brackets of the same group and 12 HA discs. The total protein concentration was assessed by the micro bicinchonic acid (Micro BCA) assay (Appendix #2).

In-solution Digestion

The equivalent of 15 μg of pellicle protein was separated from each group and placed into one polypropylene microcentrifuge tube. Dried samples were re-suspended in 50 μL of 4 M urea, 10 mM DTT and 50 mM ammonium bicarbonate at pH 7.8 and incubated for 1 hour at room temperature. Afterwards, 150 μL of 50 mM ammonium bicarbonate was added to all samples, followed by 3% (w/w) trypsin (Promega, Madison, WI, USA). Thereafter, samples were incubated for 16 h at 37 °C. Finally, the samples were dried in a rotary evaporator, de-salted by C-18 ZipTip® Pipette Tips (Millipore, Billerica, MA, USA), and subjected to mass spectrometry.

Liquid Chromatography Electrospray Ionization Tandem Mass Spectrometry (LC-ESI-MS/MS)

After trypsinization, samples were subjected to nanoscale LC-ESI-MS/MS. All samples were dried by rotary evaporator and re-suspended in 15 μL of 97.5 % H_2O /2.4% acetonitrile/0.1% formic acid and then subjected to reversed-phase LC-ESI-MS/MS. Mass spectrometric analysis was carried out with nano-HPLC Proxeon (Thermo, San Jose, CA, USA), which allows in-line liquid chromatography with the capillary column, 75 μm x 10 cm (Pico Tip™ EMITTER, New Objective, Woburn, MA) packed in-house using Magic C18 resin of 5 μm diameter and 200 Å pores size (Michrom BioResources, Auburn, CA) linked to mass spectrometer (LTQVelos, Thermo Scientific, San Jose, CA, USA) using an electrospray ionization in a survey scan in the range of m/z values 390–2000 tandem MS/MS. The nano-flow reversed-phase HPLC was developed with linear 80 minutes' gradient ranging from 5% to 55% of solvent B (97.5% acetonitrile, 0.1% formic acid) in 65 minutes at a flow rate of 300 nl/min with a maximum pressure of 280 bar. Electrospray voltage and the temperature of the ion transfer capillary were 1.8 kV and 250 °C respectively. Each survey scan (MS) was followed by automated sequential selection of

seven peptides for collision-induced dissociation (CID), with dynamic exclusion of the previously selected ions.

Data Analysis

The obtained MS/MS spectra were searched against human protein databases (Swiss Prot and TrEMBL, Swiss Institute of Bioinformatics, Geneva, Switzerland, <http://expasy.org/sprot>) using SEQUEST (PROTEOMS Discover 3.0, Thermo, San Jose, CA, USA). Search results were filtered for a false discovery rate of 1% employing a decoy search strategy utilizing a reverse database. Each sample is analyzed four consecutive time by the mass spectrometry, in order to have a positive identification of proteins, the same protein passing the filter score need to be identified from at least three different MS analysis from the same group in a total of four MS analyses per group.

RESULTS

XPS analysis of metallic orthodontic brackets are shown in Table 1 and Figure 1. We noticed that there is a huge variation in the percentage of identified elements on the analysis samples. The concentration of silver, iron, niobium, palladium and chromium were variable from one metallic bracket to the other (Table 1).

Proteome identification on the different surface materials incubated with distilled water showed a total of 356 proteins in HA control group (DMQ), 298 proteins in metallic orthodontic brackets (BMQ) and 156 proteins on ceramic orthodontic brackets (CBMQ) (Table 2; Figure 3).

Only 9 proteins were common on these three groups, 36 proteins were common between metallic brackets and HA discs; and 18 proteins were common between SS brackets and ceramic brackets (Table 3). The vast majority of these proteins were identified specifically in one group indicating little overlap in the acquired pellicle proteins (Figure 3). Effectively, 84% of proteins present on the HA discs are unique to this group, 74% were unique to ceramic brackets and 79% were unique to SS brackets.

Based on MS/MS ion count from each peptide/protein, the 20 most abundant proteins present on the SS bracket pellicle, 4 had an isoelectric point lower than 6 ($pI < 6$), 6 had a pI between 6-8 and 10 had a pI higher than 8. For the ceramic brackets, 4 proteins had a pI less than 6, 12 had a pI between 6-8 and 4 had a pI higher than 8.

The 20 most abundant proteins on each group are presented on Table 4. These proteins are selected depending on their ion count score. The higher the ion count score the higher the probability that the protein is present in the sample.

When these proteins were categorized by biological functions (Table 5), it was observed that ceramic brackets have different proteins responsible for antibacterial and antifungal properties such as immunoglobulin, S-100 and lactotransferrin when compared with HA discs and SS brackets.

Proteins responsible for remineralization of the tooth are present such as Histatin-1 for SS bracket and HA discs and protein S-100 for ceramic bracket. Statherin was also present on SS brackets. Saliva amylase, protein responsible for early plaque formation is present on ceramic brackets and

HA discs but not found on SS bracket. Inflammatory proteins such as albumin and S-100 were only found on ceramic brackets.

DISCUSSION

In this study, we characterized the atomic composition of the surface of metallic and ceramic orthodontic brackets, and identified differences among the proteins that adhere to each of the studied surfaces.

To evaluate the relationship between the surface of the material and the adherence of the proteins, XPS analysis was performed on the surface of the orthodontic brackets. The chemical composition of this surface will regulate which functional proteins species can interact with the surface (15). Therefore, this will modulate the bacteria adhesion with the molecular structure of the adsorbed protein layer (16).

While looking at the replicate experiments to analyse the surface of SS brackets, XPS results showed a high variability. This high variability on the elements may be due to the brazing process used during the fabrication of the brackets (Appendix 3).

Knowing that proteins possess different net charges, we were not surprise to see that the bracket surfaces attract proteins with positive and negative charges without preference for one over the other. The overall net charge of orthodontic brackets material is usually neutral (17,18), but we can have areas on different material that have a positive or negative charge (15). This is also reinforced by the proteome profile of the 20 most abundant proteins identified in each group, with positive and negative proteins on the surfaces of both types of brackets. However, the charge of a

protein is not the only factor that affects its interaction with a given surface. The size, structure, stability and unfolding rate of a protein plays crucial roles in their binding capacity. Furthermore, the composition of the surfaces as well as the topography, hydrophobicity and heterogeneity of the material are also factors (15) that need to be studied in the future.

In relation to protein identification, there were significant percentages of proteins that were identified specifically to each group, suggesting specificity of the protein's adsorption in relation to the surface of the bracket. As a result, biofilm formation (4) and bacterial adhesion (15) will very likely be different among the tested brackets. Because the proteins identified on the surface of the HA discs are very different from those identified on the surface of the brackets, and knowing that HA discs mimic the surface of the tooth (4), these results suggest that SS and ceramic brackets have unique protein-adsorption properties that differ from human tooth enamel. Besides finding that most proteins are unique to each bracket material, we found that, among the 20 most abundant proteins for each group, proteins responsible for antimicrobial activity, lubrication and remineralisation function are present in both bracket materials. However, inflammatory proteins and proteins responsible of dental plaque formation were found only on ceramic brackets, when the 20 most abundant proteins for each group were considered in the two different orthodontic material.

One of the proteins that was uniquely identified in the pellicle formed on the ceramic orthodontic brackets when compared with SS brackets was amylase. A previous study suggests that salivary alpha-amylase binds very selectively and with high affinity to several streptococcal species (19). This is likely to influence commensal bacterial colonization (20) and to increase the sucrase and

transferase activities of *S. mutans* (21). Furthermore, starch may intensify the adhesion of amylase-binding streptococci to dental pellicles and increase the formation of dental plaque (19). Our finding is consistent with a previous study that suggests that ceramic brackets show greater affinity for *Streptococcus mutans* when compared to metallic brackets (22).

On the other hand, mucins were found in both bracket groups. Mucins are proteins with a high carbohydrate content. MUC5B and MUC7 are the major members of the salivary mucin family (23). MUC5B is a high molecular weight gel forming mucin, has a high affinity for hydroxyapatite (24), and is a component of the acquired enamel pellicle (25). MUC7, on the other hand, is a low molecular weight monomeric mucin and demonstrated affinity for cementum (26). It also can bind to bacteria such as oral Streptococci (27). Overall, mucins play an integral role in non-immune protection (28) and they can modulate the adhesion of microorganisms to the oral tissue surfaces, and in consequence they contribute to the control of bacterial and fungal colonisation(28). Furthermore, mucins form complexes with other salivary proteins such as amylase, statherin, histatin and PRPs (29). These complexes may protect the proteins from enzymatic degradation or may enhance their function (23).

Another protein family which appears to have high affinity for ceramic surfaces are cystatins. However, no cystatins were found on SS brackets (7). Cystatins possess antimicrobial activity against oral pathogens involved in periodontal diseases such as *Aggregatibacter actinomycetemcomitans* (30). Their function also includes the formation of the acquired pellicle through their interaction with hydroxyapatite and they play an important role in maintaining the integrity of teeth (31).

In this study, histatin 1 was identified only on SS brackets. Histatin 1 possesses strong antifungal properties against *Candida albicans* (32). Furthermore, modulation of mineral formation, antibacterial activity (33,34) and protection against acid injury (35) have been reported as biological functions of histatin 1.

The initial adsorption of the proteins is an important factor for further bacteria colonization. As expected, the majority of proteins are different when the orthodontic material changes. Further investigations on bacteria adhesion depending on the bracket pellicle is needed.

CONCLUSIONS

- Our research suggests that the adsorbed protein layer, and in consequence the biofilm, will be different depending on the surface of the bracket material.
- Significant differences were noted between the different types of brackets, suggesting that there is a possibility that ceramic brackets increase the susceptibility to white spot lesions and caries.
- This study opens avenues for changes in the bracket surface as a possible way to modulate the acquired bracket pellicle to our advantage.

Chapter 3

“Key aspects for the future work”

Orthodontic brackets serve as loci for biofilm formation and create new locations for plaque retention, which increase dangerously the chances of tooth demineralization (1). In consequence, the incidence of white spot lesions was reported to be 60% in orthodontic patients (2). In some cases, orthodontic treatment must be interrupted, because of lack of oral hygiene and high prevalence of decay in the mouth, causing perfectly straight teeth with compromised oral health. If clinicians want to minimize the risk of caries and white spot lesions, it is important to emphasize on investigating protein adherence on different orthodontic materials, since proteins are the first to adsorb onto the surface of the bracket, saturating completely the surface within seconds to minutes. Later, living cells, including bacteria, will contact and interact with the molecular structure of the adsorbed protein layer forming the biofilm (3). Effectively, initial bacterial attachment is mediated by the protein pellicle composition, which can modify the surface chemistry and have an impact on bacterial adhesion (4). Therefore, understanding the modulation of the acquired pellicle when the surface of the orthodontic brackets change allows us to have a better knowledge on the future biofilm formation.

Our research suggests that the adsorbed protein layer and in consequence the biofilm will be different depending on the surface of the material because most of the proteins present on the acquired pellicle were identified specifically to each group, indicating little overlap in the acquired pellicle proteins. Furthermore, significant differences on the type of proteins responsible of dental plaque formation and maturation like amylase (5) were noted between the different types of brackets. When the 20 most abundant proteins from each group were analyzed, our results showed

that Alpha-amylase was present only on ceramic brackets. Prior studies demonstrated that salivary alpha-amylase binds very selectively and with high affinity to several streptococcal species (5). This is likely to influence commensal bacterial colonization (6) and to increase the sucrase and transferase component activities of *S. mutans* (7). Furthermore, starch may intensify the adhesion of amylase-binding streptococci to amylase in dental pellicles and increase the formation of dental plaque (5). This can be related to past literature that suggests that ceramic brackets have more affinity for *Streptococcus mutans* than metallic brackets (8).

Because of the high demand for esthetic brackets, orthodontic materials have improved drastically in that area. However, few literatures are concentrated on new ceramic and metallic brackets treated or coated with material that will decrease white spot lesions and caries. On the other hand, in the implantology field we found an evolution on multiple treated surfaces in the past 25 years (9). Surface energy, charge, composition and morphology are amongst the physicochemical characteristics which were modified during the years for a better stability and biocompatibility of the implants (9). It will be interesting in the future to have orthodontic brackets (SS and ceramic) coated with materials that absorb proteins able to repulse bacteria responsible for tooth demineralization.

For further control of cariogenic plaque, it will also be interesting to have orthodontic accessories, such as powerchains and elastics, with same physical properties but with chemical components that help decrease cariogenic biofilm accumulation and maturation. For the moment, research has reported a possible coating on the surface of SS orthodontic brackets that released sufficient Silver (Ag) ions when immersed in phosphate-buffered saline which shows significant antimicrobial potency against *Streptococcus mutans* and *Aggregatibacter actinomycetemcomitans* strains (10).

Some authors also report fluoride-releasing materials (11,12) to reduce the risk of developing a white spot lesions around the orthodontic bracket. However, Nascimento concluded by warning orthodontists that there is limited evidence to support the use of fluoride-releasing materials in order to prevent white spot lesions development (11). Furthermore, a review on prevention and treatment of white spot lesions mentions that multiple recent narrative and systematic reviews have failed to present sufficient evidence for most preventive measures against white spot lesions, except for the topical application of fluoride-containing products (13). However, fluoride mouthwash and fluoride toothpaste have the disadvantage to be patient-dependant. It has been shown that only 13% of the patients comply fully with the fluoride recommendations (14). These data highlight the importance of developing modified fluoride-releasing materials instead of depending on the “good hygiene” of our patients.

New area of research, including proteomics allows us to study the protein pellicle with precision. This new science is very promising to help us understand better the relationship between oral biofilm and oral disease with the objective of providing information on potential targets for biofilm interruption and advance with new antimicrobial materials.

This study, is very relevant because it opens avenues on the not yet characterized changes on the bracket surface and the possible ways to modulate the acquired bracket pellicle in our advantage. In a near future, we hope to see new materials able to prevent cariogenic biofilm adhesion, and to attract proteins that can promote tooth remineralization to the bracket surface. This will have a big impact on the oral health of orthodontic patients.

E7ER44	Lactotransferrin	50.07	77.92
F5GZK2	Collagen alpha-1(XXI) chain	49.95	99.23
A0M8Q6	Immunoglobulin lambda constant 7	45.56	11.25
P04080	Cystatin-B	44.73	11.13
B4DW52	cDNA FLJ55253, highly similar to Actin, cytoplasmic 1	43.69	38.61
P13645	Keratin, type I cytoskeletal 10	41.19	58.79
B1AN48	Small proline-rich protein 3	39.34	16.95
P28325	Cystatin-D	38.76	16.07
A0A0A0MQW7	Leukocyte immunoglobulin-like receptor subfamily B member 4	38.27	14.44
Q0QET7	Glyceraldehyde-3-phosphate dehydrogenase	37.96	24.60
J3KNQ2	Fibronectin type III domain-containing protein 1	36.62	194.42
K7ESB7	Dedicator of cytokinesis protein 6	34.95	148.70
Q92954	Proteoglycan 4	33.41	150.98
G3V1A4	Cofilin 1 (Non-muscle), isoform CRA_a	33.14	16.80
E9PCT1	Serine/arginine repetitive matrix protein 1	25.61	93.38
A8K781	cDNA FLJ75299, highly similar to Xenopus laevis proteasome (prosome, macropain) 26S subunit, ATPase 3, mRNA	22.25	47.29
P31025	Lipocalin-1	21.55	19.24
Q7Z351	Putative uncharacterized protein DKFZp686N02209	20.15	52.82
V9HWC6	Peptidyl-prolyl cis-trans isomerase	19.72	22.73
Q1RMC9	ERBB2IP protein	19.23	153.42
A8K2I0	cDNA FLJ78504, highly similar to Homo sapiens keratin 6A (KRT6A), mRNA	18.91	59.99
A0A0J9YYJ7	Unconventional myosin-XVB	18.26	79.47
Q8WYG9	G-protein coupled receptor 98	17.79	692.64
B7Z830	cDNA FLJ61741, highly similar to HIRA protein	17.13	63.97
A0A087X1X8	Uncharacterized protein	17.12	21.74
B4E1B2	cDNA FLJ53691, highly similar to Serotransferrin	16.95	74.78
H7C517	Adenylate kinase 9	16.94	87.28
A0A087WW06	Tetratricopeptide repeat protein 28	16.70	256.71
C9JFF0	Kinesin-like protein KIF26A	16.48	180.04
Q59FL8	Receptor protein-tyrosine kinase	16.08	119.87
I0B0K8	Truncated profilaggrin	15.94	430.16
Q7Z5P9	Mucin-19	15.85	804.77
Q8WYP5	Protein ELYS	15.45	252.34
E1A689	Mutant Apo B 100	15.11	489.51

A0A0G2JRN3	Alpha-1-antitrypsin	14.72	40.21
E9PAV3	Nascent polypeptide-associated complex subunit alpha, muscle-specific for	14.61	205.29
P35527	Keratin, type I cytoskeletal 9	14.55	62.03
Q8TEA3	cDNA FLJ23738 fis, clone HEP15081, highly similar to PDZ domain-containing guanine nucleotide exchange factor I	14.54	126.03
B4E223	cDNA FLJ52075, moderately similar to Mus musculus SPT2, Suppressor of Ty, domain containing 1, mRNA	14.21	68.46
Q8N4F0	BPI fold-containing family B member 2	14.16	49.14
P49639	Homeobox protein Hox-A1	14.01	36.62
E7EVA0	Microtubule-associated protein	13.84	245.29
H9KV90	SH3 and multiple ankyrin repeat domains protein 1	13.51	225.76
T1S9D5	MUC5AC	13.45	521.30
Q8IVF2	Protein AHNAK2	13.23	616.24
Q86Y00	GTF2IRD2B protein	13.16	50.83
P10599	Thioredoxin	12.98	11.73
B7Z8H1	cDNA FLJ54814	12.92	24.15
B3KX86	cDNA FLJ44973 fis, clone BRAWH3001638	12.84	125.22
B2RNR6	Zinc finger RNA binding protein	12.52	116.94
B7ZLW1	CAMSAP1 protein	11.83	163.16
O15083	ERC protein 2	11.73	110.49
K7EJ44	Profilin	11.55	11.38
Q5CZC0	Fibrous sheath-interacting protein 2	11.49	780.12
Q5TAX3	Terminal uridylyltransferase 4	11.41	185.05
Q12830	Nucleosome-remodeling factor subunit BPTF	11.22	338.05
J3KPS2	Protein FAM83H	11.03	96.39
Q10571	Transcriptional activator MN1	10.98	135.92
H0Y9N7	Inhibitor of Bruton tyrosine kinase	10.90	14.09
Q5JPC9	ABI gene family, member 3 (NESH) binding protein, isoform CRA_d	10.38	110.61
H3BTR6	RNA-binding protein with serine-rich domain 1	10.27	12.99
A0A024QZH6	Serine arginine-rich pre-mRNA splicing factor SR-A1, isoform CRA_a	10.05	139.18
A4FUT8	JMJD1B protein	10.00	168.95
K7EL96	Perilipin-3	9.98	17.95
Q8TD20	Solute carrier family 2, facilitated glucose transporter member 12	9.93	66.92
A0A0G2JQF2	Formimidoyltransferase-cyclodeaminase	9.93	45.46
P54687	Branched-chain-amino-acid aminotransferase, cytosolic	9.86	42.94
B4DIS5	cDNA FLJ50076, highly similar to Liprin-alpha-4	9.84	103.07

Q9NR48	Histone-lysine N-methyltransferase ASH1L	9.81	332.58
P04275	von Willebrand factor	9.77	309.06
B4DUY9	cDNA FLJ56362	9.64	67.89
B4DHH1	cDNA FLJ57930, highly similar to Homo sapiens RAS guanyl releasing protein 1 (calcium and DAG-regulated) (RASGRP1), mRNA	9.42	85.17
A0A0C4DGV9	DNA ligase	9.19	96.15
B3KR01	cDNA FLJ33378 fis, clone BRACE2006354	8.90	46.07
J7M2B1	Tyrosine-protein kinase receptor	8.43	98.89
P25391	Laminin subunit alpha-1	8.36	336.87
Q5VST9	Obscurin	8.33	867.94
Q96L91	E1A-binding protein p400	8.04	343.28
Q8WXE0	Caskin-2	8.03	126.71
Q5T112	tRNA (adenine(37)-N6)-methyltransferase	7.96	17.35
A4PB67	YY1AP-related protein1	7.72	248.19
P80511	Protein S100-A12	7.56	10.57
Q6ZQQ6	WD repeat-containing protein 87	7.54	332.97
U3KPZ7	Uncharacterized protein	7.54	114.47
A7MBM6	MLL3 protein	7.40	362.42
A0A0A0MRS7	Ankyrin repeat and SAM domain-containing protein 6	7.10	62.27
J3KRI5	Cadherin-8	7.06	82.70
J3KQ96	Treacle protein	7.04	144.04
B2RMV2	CYTSA protein	6.98	124.50
D6RHX1	Mucin-7	6.94	15.45
B4E1M1	cDNA FLJ60391	6.86	73.88
F5GX59	Zonadhesin	6.84	282.23
H0Y6B5	Abl interactor 2	6.83	31.86
Q9Y608	Leucine-rich repeat flightless-interacting protein 2	6.82	82.12
E9PIQ4	Mth938 domain-containing protein	6.82	9.98
E9PPH6	Exophilin-5	6.77	192.96
Q9Y4D8	Probable E3 ubiquitin-protein ligase HECTD4	6.75	439.07
Q4G0P3	Hydrocephalus-inducing protein homolog	6.69	575.53
E5RIQ7	Eyes absent homolog	6.63	23.33
Q16880	2-hydroxyacylsphingosine 1-beta-galactosyltransferase	6.63	61.40
E9PCK9	Muscular LMNA-interacting protein	6.62	59.08
Q9P0X4	Voltage-dependent T-type calcium channel subunit alpha-1I	6.61	244.95
K7N7B3	Synaptonemal complex protein 2-like	6.59	93.44
Q6ZP01	RNA-binding protein 44	6.53	117.91
Q09666	Neuroblast differentiation-associated protein AHNAK	6.51	628.70

B3KY59	cDNA FLJ46903 fis, clone MESAN2003661, highly similar to Cdc42 effector protein 3 (Binder of Rho GTPases 2)	6.50	27.63
A8K5B3	cDNA FLJ76829, highly similar to Homo sapiens piggyBac transposable element derived 1 (PGBD1), mRNA	6.46	92.39
Q9BXW9	Fanconi anemia group D2 protein	6.44	164.02
H9NIL3	G protein-coupled receptor 20	6.42	38.64
G3V207	Transmembrane and coiled-coil domain family 3, isoform CRA_c	6.35	50.14
B4E2E5	cDNA FLJ56289, highly similar to Homo sapiens sperm specific antigen 2 (SSFA2), mRNA	6.34	119.13
Q96N67	Dedicator of cytokinesis protein 7	6.31	242.41
E9PNY3	Serine/threonine-protein phosphatase 2A 56 kDa regulatory subunit beta isoform	6.31	21.89
H0Y5R1	Aryl hydrocarbon receptor nuclear translocator-like protein 2	6.30	65.63
A0A0A0MQR4	Protein capicua homolog	6.29	163.58
Q9NTI5	Sister chromatid cohesion protein PDS5 homolog B	6.17	164.56
Q96BY6	Dedicator of cytokinesis protein 10	6.10	249.37
A0A140VJG7	Component of oligomeric golgi complex 6, isoform CRA_a	5.88	68.37
Q9NPV6	Putative uncharacterized protein DKFZp762E1511	5.86	17.77
Q8N8K9	Uncharacterized protein KIAA1958	5.75	79.16
J3QT10	N-lysine methyltransferase SETD6	5.67	45.57
Q9C0G0	Zinc finger protein 407	5.47	247.21
A0A0A0MRY1	Structural maintenance of chromosomes protein 6	5.27	50.91
D6RG39	OCIA domain-containing protein 1	5.01	19.01
Q96RW7	Hemicentin-1	4.98	613.00
A7MD03	CCDC132 protein	4.98	110.28
Q8WVS4	WD repeat-containing protein 60	4.93	122.50
Q96HA1	Nuclear envelope pore membrane protein POM 121	4.86	127.64
H0Y4R5	Transmembrane protein 201	4.82	59.80
Q8NB66	Protein unc-13 homolog C	4.78	250.75
H0Y4C5	NGFI-A-binding protein 1	4.75	27.75
Q59GI4	Zinc finger, FYVE domain containing 9 isoform 3 variant	4.69	145.96
E7EX73	Eukaryotic translation initiation factor 4 gamma 1	4.63	158.55
Q9BTC0	Death-inducer obliterator 1	4.31	243.72
A6NNC1	Putative POM121-like protein 1-like	4.14	94.00
DMQ			

Accession Number	Description (protein name)	Ion count score	MW [kDa]

Research Ethics

**Western University Health Science Research Ethics Board
HSREB Annual Continuing Ethics Approval Notice**

Date: June 06, 2016

Principal Investigator: Dr. Walter Siqueira

Department & Institution: Schulich School of Medicine and Dentistry\Dentistry, Western University

Review Type: Expedited

HSREB File Number: 6251

Study Title: Composition, Structure and Function of Salivary Proteins

Sponsor: Natural Sciences and Engineering Research Council

HSREB Renewal Due Date & HSREB Expiry Date:

Renewal Due -2017/05/31

Expiry Date -2017/06/25

The Western University Health Science Research Ethics Board (HSREB) has reviewed the Continuing Ethics Review (CER) Form and is re-issuing approval for the above noted study.

The Western University HSREB operates in compliance with the Tri-Council Policy Statement Ethical Conduct for Research Involving Humans (TCPS2), the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use Guideline for Good Clinical Practice (ICH E6 R1), the Ontario Freedom of Information and Protection of Privacy Act (FIPPA, 1990), the Ontario Personal Health Information Protection Act (PHIPA, 2004), Part 4 of the Natural Health Product Regulations, Health Canada Medical Device Regulations and Part C, Division 5, of the Food and Drug Regulations of Health Canada.

Members of the HSREB who are named as Investigators in research studies do not participate in discussions related to, nor vote on such studies when they are presented to the REB.

The HSREB is registered with the U.S. Department of Health & Human Services under the IRB registration number IRB 00000940.

CURRICULUM VITAE

Maria Pia Canales, DMD

Languages: Fluent in French, English and Spanish

EDUCATION

2015 – 2018 WESTERN UNIVERSITY	Master of Clinical Dentistry (MCID)
2012-2013 BOSTON UNIVERSITY	Certificate in Advanced General Studies (AEGD)
2007 - 2012 UNIVERSITÉ DE MONTRÉAL	<i>DMD – Doctor of Dental Medicine</i> <i>- Honors received by ‘ADQPPA’</i>
2004 - 2006 COLLÈGE JEAN-DE-BRÉBEUF	D.E.C. – College Degree in Natural Science
1999 - 2004 COLLÈGE DUROCHER ST-LAMBERT	D.E.S. High School Diploma

PROFESSIONAL EXPERIENCE

2013 – 2015 CLINIQUE RUE ROY	General Dentist
May 2012 UNIVERSITÉ DE MONTRÉAL	Oral and maxillofacial surgery assistant Continuing dental education
2004 – 2006 COLLEGE JEAN-DE-BRÉBEUF	Mathematics and physics tutor

ACTIVITIES

2013 – 2015 DENTISTE SANS FRONTIÈRE	Active Member -Fundraising and providing dental care in developing countries
---	--

2004-2006

AMNESTY INTERNATIONAL

Active Member

-Campaigning for human rights

2004 à 2006

SAINTE-JUSTINE HOSPITAL

Volunteer

-Help parents move to Ronald McDonald residence

-Provide moral support to the parents of the patients

PERSONNEL INTEREST

Volley-ball, yoga, running, cycling and cooking
