Abstract

The strength reduction factors, \( \phi \), defined in ACI 318-14 for different structural actions and elements lead to inconsistent results. This study proposes partial material strength reduction factors for concrete, \( \phi_c \), and reinforcing steel, \( \phi_s \), that yield similar design strengths and more consistent reliability indices. Three structural actions are investigated: moment; shear; and, combined moment and axial force. The first-order, second-moment method is used to compute reliability indices for moment and shear, and Monte Carlo simulation is used for combined moment and axial force. The statistical parameters assumed for the professional factor for shear strength significantly impact the reliability indices. Although no single combination of \( \phi_s \) and \( \phi_c \) is the best for these three actions, the recommended partial material strength reduction factors are \( \phi_s \) of 0.90 and \( \phi_c \) of 0.60, or for spirally reinforced columns, 0.70. Alternatively, for shear, the combination with \( \phi_s \) of 0.80 and \( \phi_c \) of 0.65 is recommended.

Keywords

reinforced concrete; partial material strength reduction factors; moment; shear; slabs; beams; columns; design strengths; reliability.
Acknowledgments

I would like to express my sincere appreciation to my supervisor, Dr. Michael Bartlett for providing me with the opportunity to do this research. His educational and research experience allowed me to learn various knowledge, his earnestness and preciseness encouraged me to be strict with myself, and his patience made me overcome difficulties.

I also appreciate the colleagues and professors who inspired me.

I thank The University of Western Ontario for providing financial support in the form of the Western Graduate Research Scholarship, Western Graduate Research Assistance, Graduate Research Assistantship, and Graduate Teaching Assistantship. Financial support through Dr. Bartlett’s NSERC Discovery Grant is also gratefully acknowledged.

Finally, I am grateful to my family for their encouragement.

### Notation

- \( a \) depth of equivalent rectangular stress block in ACI 318-14
- \( a_r \) depth of equivalent rectangular stress block for partial material strength reduction factors format
- \( a_v \) shear span, equal to distance from center of concentrated load to either: (a) face of support for continuous or cantilevered members, or (b) center of support for simply supported members
- \( A \) area of compression segment of circular section
- \( A_g \) gross area of section
- \( A_i \) structural load
- \( A_s \) area of nonprestressed longitudinal tension reinforcement
- \( A_{si} \) area of the \( i \)th layer of reinforcement
- \( A_{st} \) total area of nonprestressed longitudinal reinforcement
- \( A_v \) area of shear reinforcement within spacing \( s \)
- \( A\bar{y} \) moment of compression segment about center of circular section
- \( b \) width of compression face of member
- \( b_w \) web width
- \( B_i \) modeling parameter
- \( c \) distance from extreme compression fiber to neutral axis
- \( c_i \) influence coefficient
- \( C_c \) nominal compressive force in concrete
- \( C_{ij} \) name of strength reduction factor combination
- \( C_{rc} \) factored compressive force in concrete for partial material strength reduction factors format
- \( d \) effective depth, equal to distance from extreme compression fiber to centroid of longitudinal tension reinforcement
- \( d_i \) distance from extreme compression fiber to the \( i \)th layer of reinforcement, where \( i = 1 \) refers to the reinforcement located furthest
- \( d_t \) distance from extreme compression fiber to extreme layer of tension steel
- \( D \) effect of service dead load
- \( D_i \) simulated value of dead load
$e$  eccentricity
$e_l$  simulated value of eccentricity
$e_r$  design eccentricity for partial material strength reduction factors format, equal to $M_r/P_r$
$e_{r\text{bal}}$  eccentricity corresponding to balanced failure for partial material strength reduction factors format
$(e_{r\text{bal}})_{\text{max}}$  maximum eccentricity corresponding to balanced failure for partial material strength reduction factors format
$(e_{r\text{bal}})_{\text{min}}$  minimum eccentricity corresponding to balanced failure for partial material strength reduction factors format
$e_u$  design eccentricity for ACI 318-14, equal to $\phi M_n/\phi P_n$
$e_{u\text{bal}}$  eccentricity corresponding to balanced failure for ACI 318-14
$(e_{u\text{bal}})_{\text{max}}$  maximum eccentricity corresponding to balanced failure for ACI 318-14
$(e_{u\text{bal}})_{\text{min}}$  minimum eccentricity corresponding to balanced failure for ACI 318-14
$E_s$  modulus of elasticity of reinforcement
$f(\bullet)$  function of resistance or load effect in limit state function
$f_{c'}$  specified compressive strength of concrete
$f_c^*$  reduced compressive strength of concrete
$f_{c,i-p}$  in-place compressive strength of concrete
$f_s$  stress in reinforcement at service loads
$f_s^*$  reduced stress in reinforcement
$f_{si}$  stress in the $i$th layer of reinforcement
$f_y$  specified yield strength for nonprestressed reinforcement
$f_y^*$  reduced yield strength for nonprestressed reinforcement
$f_{yt}$  specified yield strength of transverse reinforcement
$F_{i-p}$  factor to account for variation of in-place strength
$F_r$  factor to account for rate-of-loading effects
$F_{rsi}$  factored force in the $i$th layer of reinforcement for partial material strength reduction factors format
$F_{si}$  nominal force in the $i$th layer of reinforcement
$F_1$  ratio of mean 28-day control cylinder strength to specified 28-day strength
$F_2$  
\text{ratio of mean in-place strength at 28 days to mean 28-day cylinder strength}

g(\bullet)  
\text{limit state function}

$G$  
\text{geometric property}

$h$  
\text{overall thickness, height, or depth of member}

$l$  
\text{span length of member}

$L$  
\text{effect of service live load}

$L_i$  
\text{simulated value of live load}

$M$  
\text{material strength property}

$M_i$  
\text{simulated value of flexural strength}

$M_n$  
\text{nominal flexural strength at section}

$M_r$  
\text{design flexural strength for partial material strength reduction factors format}

$M_u$  
\text{factored moment at section}

$n$  
\text{number of samples}

$P$  
\text{professional factor}

$P_f$  
\text{probability of failure}

$P_i$  
\text{simulated value of axial strength}

$P_n$  
\text{nominal axial strength of member}

$P_{n,\text{max}}$  
\text{maximum nominal axial compressive strength of member}

$P_{nt}$  
\text{nominal axial tensile strength of member}

$P_r$  
\text{design axial strength for partial material strength reduction factors format}

$P_{r,\text{max}}$  
\text{maximum design axial compressive strength for partial material strength reduction factors format}

$P_{rt}$  
\text{design axial tensile strength for partial material strength reduction factors format}

$P_u$  
\text{factored axial force}

$Q$  
\text{load effect in limit state function, mean} = \bar{Q}, \text{ standard deviation} = \sigma_Q, \text{ coefficient of variation} = V_Q

$Q_i$  
\text{load effect for the} \text{ith type load}

$Q_M$  
\text{load effect in limit state function for flexural member}

$Q_V$  
\text{load effect in limit state function for member resisting shear force}

$R$  
\text{resistance in limit state function, mean} = \bar{R}, \text{ standard deviation} = \sigma_R,
coefficient of variation = $V_R$

\( R_M \) resistance in limit state function for flexural member

\( R_V \) resistance in limit state function for member resisting shear force

\( s \) center-to-center spacing of transverse reinforcement

\( S_n \) nominal strength

\( T_D \) factor to account for transformation from dead load to dead load effect

\( T_{Di} \) simulated value of transformation from dead load to dead load effect

\( T_L \) factor to account for transformation from live load to live load effect

\( T_{Li} \) simulated value of transformation from live load to live load effect

\( U \) required strength computed using factored load combinations

\( V \) coefficient of variation

\( V_c \) nominal shear strength provided by concrete

\( V_n \) nominal shear strength

\( V_r \) design shear strength for partial material strength reduction factors format

\( V_{rc} \) design shear strength provided by concrete for partial material strength reduction factors format

\( V_{rs} \) design shear strength provided by shear reinforcement for partial material strength reduction factors format

\( V_s \) nominal shear strength provided by shear reinforcement

\( V_u \) factored shear force at section

\( w_D \) specified dead load per unit length

\( w_L \) specified live load per unit length

\( X_i \) resistance or load variable, mean = $\bar{X}_i$, standard deviation = $\sigma_{X_i}$

\( X_i^* \) resistance or load variable at linearizing point

\( Z \) ratio of strain in extreme tension layer of reinforcement to yield strain

\( Z \) limit state function, mean = $\bar{Z}$, standard deviation = $\sigma_Z$

\( \alpha_M \) design flexural strength ratio, equal to design flexural strength obtained using strength reduction factors in ACI 318-14 to that obtained using partial material strength reduction factors

\( \alpha_{PM} \) design combined flexural and axial strength ratio, equal to design combined flexural and axial strength obtained using strength reduction factors in ACI
318-14 to that obtained using partial material strength reduction factors

\( \alpha_V \) design shear strength ratio, equal to design shear strength obtained using strength reduction factors in ACI 318-14 to that obtained using partial material strength reduction factors

\( \beta \) reliability index

\( \beta_M \) reliability index for moment

\( \beta_{Mr} \) reliability index for moment obtained using partial material strength reduction factors

\( \beta_{Mu} \) reliability index for moment obtained using strength reduction factors in ACI 318-14

\( \beta_{PM} \) reliability index for combined moment and axial force

\( \beta_{PMr} \) reliability index for combined moment and axial force obtained using partial material strength reduction factors

\( \beta_{PMu} \) reliability index for combined moment and axial force obtained using strength reduction factors in ACI 318-14

\( \beta_V \) reliability index for shear

\( \beta_{Vr} \) reliability index for shear obtained using partial material strength reduction factors

\( \beta_{Vu} \) reliability index for shear obtained using strength reduction factors in ACI 318-14

\( \beta_1 \) factor relating depth of equivalent rectangular compressive stress block to depth of neutral axis

\( \gamma \) ratio of distance between outer layers of reinforcement in column to overall column depth

\( \delta \) bias coefficient

\( \varepsilon_{cu} \) maximum usable strain at extreme concrete compression fiber

\( \varepsilon_{ai} \) strain in the \( i \)th layer of reinforcement, where \( i = 1 \) refers to the reinforcement located furthest from extreme compression fiber

\( \varepsilon_t \) net tensile strain in extreme layer of longitudinal tension reinforcement at nominal strength

\( \varepsilon_{cy} \) yield strain in extreme layer of longitudinal tension reinforcement
yield strain of reinforcement, equal to $f_y/E_s$

angle used to calculate compression segment of circular column

modification factor to account for reduced shear strength of lightweight concrete

longitudinal reinforcement ratio, equal to ratio of $A_s$ to $bd$

total reinforcement ratio, equal to ratio of total longitudinal reinforcement area to cross-sectional area of column

transverse reinforcement ratio, equal to ratio of area of distributed transverse reinforcement to gross concrete area perpendicular to that reinforcement

standard deviation

strength reduction factor in ACI 318-14

partial material strength reduction factor for concrete

partial material strength reduction factor for reinforcing steel

design flexural strength in ACI 318-14

design axial strength in ACI 318-14

maximum design axial compressive strength in ACI 318-14

design axial tensile strength in ACI 318-14

design shear strength in ACI 318-14

cumulative distribution function of standard normal distribution
Chapter 1

1 Introduction

1.1 Introduction

In the current Building Code Requirements for Structural Concrete (ACI 318-14) and Commentary (ACI 318R-14) (ACI Committee 318 2014), the basic requirement for strength design is

$$\phi S_n \geq U$$  \hspace{1cm} [1.1]

where: $\phi$ is the strength reduction factor; $S_n$ is the nominal strength; and, $U$ is the required strength computed using the factored load combinations. The overall strength reduction factor, $\phi$, accounts for “the probability of understrength due to variations of in-place material strengths and dimensions, the effect of simplifying assumptions in the design equations, the degree of ductility, potential failure mode of the member, the required reliability, and significance of failure and existence of alternative load paths for the member in the structure” (ACI Committee 318 2014).

For members resisting moment, axial force, combined moment and axial force, or shear, Table 1.1 shows strength reduction factors, $\phi$, defined in Chapter 21 of ACI 318-14. The strength reduction factor for shear equals 0.75, while for moment, axial force, or combined moment and axial force, the strength reduction factor ranges from 0.65 to 0.90. The additional requirements shown in Table 1.2, which is identical to Table 21.2.2 in ACI 318-14, need to be applied to determine the exact value for a specific combination of moment and axial force for spirally reinforced or tied columns. The strength reduction factor in these cases depends on the net tensile strain in the extreme layer of longitudinal reinforcement, $\varepsilon_t$, which is determined assuming a linear strain distribution and a strain in the extreme compression fiber of 0.003 at nominal strength. This is shown in Figure 1.1, which is identical to Fig. R21.2.2a in ACI 318R-14. If $\varepsilon_t$ is greater than or equal to 0.005, the section is defined as tension-controlled, or if it is less than or equal to $\varepsilon_{ty}$, the section is compression-controlled, where $\varepsilon_{ty}$ is the yield strain in the extreme tension layer of
reinforcement, equal to \( f_y/E_s \) for deformed reinforcement, \( f_y \) is the specified yield strength for nonprestressed reinforcement, and \( E_s \) is the modulus of elasticity of reinforcement. Between the two limits of 0.005 and \( \varepsilon_{ty} \), a transition occurs between the strength reduction factor for moment for lightly reinforced sections, 0.90, and that for axial force combined with moment, 0.65 or 0.75 for tied or spirally reinforced columns, respectively. This is shown in Figure 1.2, which is identical to Fig. R21.2.2b in ACI 318R-14.

The overall strength reduction factor presented in ACI 318-14, \( \phi \), has some shortcomings that have been identified by others, as follows:

1. For a member subjected to combined moment and axial force, an odd variation happens within the transition region (e.g., Gamble 1998, 2015). Figure 1.3, which is similar to figures generated by Gamble (2015) shows the interaction diagrams for a 325 mm square column with eight bars distributed equally in four faces. The ratio of the distance between the outer layers of reinforcement in a column to the overall column depth, \( \gamma \), is 0.6 and the ratio of total reinforcement area to the cross-sectional area of column, \( \rho_g \), is 0.01. The specified compressive strength of concrete, \( f_{c'} \), and \( f_y \) are 25 MPa and 420 MPa, respectively. The interaction diagram derived using the strength reduction factors in ACI 318-14 shows an inconsistency in the transition region compared to the nominal strength interaction diagram. If partial material strength reduction factors are applied, e.g. \( f_{c'}^* = 0.6f_{c'} \) and \( f_y^* = 0.9f_y \) (\( f_s^* = 0.9f_s \)) recommended by Gamble (2015), the inconsistency disappears, where \( f_{c'}^* \) is the reduced compressive strength of concrete, \( f_y^* \) is the reduced yield strength for nonprestressed reinforcement, \( f_s \) is the stress in reinforcement at service loads, and \( f_s^* \) is the reduced stress in reinforcement.

Similarly, Figure 1.4 is generated for a 325 mm diameter circular column with eight evenly distributed bars and ties. Similar to the square column, the current ACI 318-14 strength reduction factors create an awkward transition that is eliminated when the partial reduced material strengths are used (Gamble 2015).
2. Figure 1.5, originally created by Lequesne and Pincheira (2014), shows the design interaction diagram obtained using ACI 318-11 strength reduction factors which are identical to those for ACI 318-14, for an L-shaped wall section. In this case and for other sections with wide flanges, the results are again unreasonable: on the right side of point B, the flexural and axial strengths increase simultaneously with the increasing eccentricity when the compression zone stress block extends into the web and $\varepsilon_{cy} \leq \varepsilon_t \leq 0.005$. The reason for the increasing design axial strength, $\phi P_n$, with the increasing eccentricity is that $\phi$ increases at a proportionally higher rate than the nominal axial strength, $P_n$, decreases. This results in non-unique moment capacities for one axial strength level between points A and B as shown (Lequesne and Pincheira 2014).

3. For members subjected to shear, the statistical parameters for professional factor have significant changed. The professional factor is defined as a value observed experimentally divided by the value predicted using the actual geometric and material properties and so quantities the accuracy of an equation for resistance. For example, the bias coefficient and coefficient of variation of the professional factor reported by Somo and Hong (2006) are equal to 1.47 and 0.36, respectively, for beams with stirrups and shear span-to-depth ratio larger than or equal to 2. In the original calibration of the ACI strength reduction factors, values of 1.09 and 0.12 were adopted by Israel et al. (1987). Similar values of 1.075 and 0.10 were recommended by Nowak and Szerszen (2003). These changes may significantly affect the reliability, so the strength reduction factor needs to be reevaluated. Specifically the higher bias coefficient reported by Somo and Hong (2006) will increase the reliability and so permit use of a greater strength reduction factor. The higher coefficient of variation, however, has the opposite effect.

4. A single overall value of $\phi$ cannot clarify the contributions of concrete and reinforcing steel, and variabilities of their strengths, so partial material strength reduction factors may yield advantages for reinforced concrete (Israel et al. 1987).
It is noteworthy that Canadian Standard CSA-A23.3 “Design of Concrete Structures” (CSA 2014) has used partial resistance factors for the concrete and steel material strengths since 1984.

1.2 Objective

The objective of this study is to select partial material strength reduction factors for concrete and reinforcing steel that yield similar design strengths to those obtained using the current ACI 318-14 provisions. Similarly, the reliability indices corresponding to the proposed strength reduction factors should be similar to or more appropriate than those corresponding to the current provisions.

Three structural actions acting on nonprestressed members shall be investigated: moment; one-way shear; and, combined moment and axial force. For members subjected to moment, the full range of flexural reinforcement ratios, corresponding to those in two-way slabs, one-way slabs and beams shall be investigated. Similarly, for members subjected to one-way shear, a realistic range of shear reinforcement ratios shall be investigated. For members subjected to combined moment and axial force, realistic total reinforcement ratios and reinforcement arrangements in the cross sections shall be investigated. Design strengths will be compared based on the current and partial material strength reduction factors. Statistical parameters related to the reliability index calculation will be collected from the literature. The first-order, second-moment (FOSM) reliability analysis method will be applied for members subjected to moment or shear. Monte Carlo simulation will be used to determine the reliability of members subjected to combined moment and axial force because of the complexity of the equations necessary to generate interaction diagrams.

1.3 Outline

In Chapter 2, potential partial material strength reduction factors that yield similar design strengths as the current ACI 318-14 provisions are investigated. For members subjected to moment, the design strengths of singly reinforced two-way slabs, one-way slabs and beams corresponding to ACI 318-14 and the partial material strength reduction factors
are calculated for different concrete compressive strengths, $f_{c'}$, and ratios of nonprestressed longitudinal tension reinforcement, $\rho$. For members subjected to one-way shear, the design strengths of beams with different transverse reinforcement ratios, $\rho_t$, and $f_{c'}$ are studied. For members subjected to combined moment and axial force, five column sections are investigated: square section with three bars in each face; square section with three bars in two end faces only; square section with three bars in two side faces only; circular section with eight evenly distributed bars and ties; and, circular section with eight evenly distributed bars and spiral reinforcement. For each column section, different $\gamma, f_{c'}$, and $\rho_b$ are studied. For each structural action, appropriate partial material strength reduction factors are proposed.

Chapter 3 presents the reliability model and the first-order, second-moment (FOSM) method. It then summarizes statistical parameters for geometric properties, material strengths, professional factors and load effects collected from the literature. The calculated reliability indices for members subjected to moment or one-way shear are presented for the different geometric and material properties, and two live-to-dead load ratios. Partial material strength reduction factors are then proposed based on the reliability analyses and the results obtained in Chapter 2.

Chapter 4 presents the reliability analyses for columns conducted by Monte Carlo simulation. Different geometric and material properties, and two live-to-dead load ratios are investigated. The applied moment and axial force are assumed perfectly correlated and reliability indices are computed for a range of specific eccentricities. Again, appropriate partial material strength reduction factors are proposed based on the reliability analyses and the results obtained in Chapter 2.

Chapter 5 presents the summary, conclusions, and suggestions for future work.

Appendices A, B and C present supplementary tables, figures and Matlab (Version R2016b; The Mathworks, Inc. 2016) codes that complement the material presented in Chapters 2, 3 and 4, respectively.

2 Derivation of Partial Material Strength Reduction Factors Based on Design Strengths

2.1 Introduction

Chapter 21 of Building Code Requirements for Structural Concrete (ACI 318-14) and Commentary (ACI 318R-14) (ACI Committee 318 2014) specifies an overall strength reduction factor, $\phi$, for reinforced concrete elements, based on the structural action being resisted. The overall objective of this thesis is to propose partial material strength reduction factors for concrete and reinforcing steel that are independent of the structural action.

The objective of this chapter is to identify suitable partial material strength reduction factors that best duplicate the design strengths obtained using the current ACI 318-14 provisions. The preliminary results obtained in this chapter indicate the potential ranges of the best partial material strength reduction factors, and the final decision will be made after conducting reliability analyses presented in Chapters 3 and 4.

2.2 Methodology

This chapter develops partial material strength reduction factors for cross sections resisting three structural actions: moment; one-way shear; and, combined moment and axial force. For each action, design strengths are computed using ACI 318-14 and various partial material strength reduction factors, $\phi_c$ for concrete and $\phi_s$ for reinforcing steel. Table 2.1 shows the sixteen partial material strength reduction factor combinations considered in this study. The $C_{ij}$ notation shown represents a particular combination, where $i$ is the $i$-th value of $\phi_c$ and $j$ is the $j$-th value of $\phi_c$.

The calculations are conducted using Microsoft Excel (Version 2013; Microsoft 2013) and Matlab (Version R2016b; The Mathworks, Inc. 2016) to compute the design strength ratio, which is defined as the design strength obtained using the strength reduction factor in ACI 318-14 to that obtained using a particular pair of partial material strength
reduction factors. Design strength ratios greater than 1 represent cases where the ACI 318-14 design strengths exceed those computed using the proposed values, and so indicate that the proposed values are more conservative. For this investigation, the best combination of partial material strength reduction factors will give design strengths that most closely approximate those obtained using the current ACI 318-14 provisions. This corresponds to the mean design strength ratio approaching 1 with the least standard deviation. Reliability analyses based on these preliminary results will be presented in Chapters 3 and 4.

2.3 Moment

This section presents proposed partial material strength reduction factors that most closely approximate the design flexural strengths obtained using the ACI 318-14 criteria. The ranges of geometric and material parameters are quantified and the design flexural strength equations corresponding to the current ACI 318-14 and the partial material strength reduction factors formats are presented. Typical design flexural strength ratios, $\alpha_M$, for each combination of partial material strength reduction factors are presented, and the means and standard deviations for each combination are quantified. The sensitivities of the design flexural strength ratios to the partial material strength reduction factors, for various geometric and material properties are investigated. The best factor combinations are recommended.

2.3.1 Geometric and Material Properties

The investigation of moment is limited to rectangular singly reinforced cross sections designed based on ACI 318-14 with a specified reinforcement yield strength, $f_y$, of 420 MPa and specified concrete compressive strengths, $f'_c$, of 25 and 45 MPa. These material strengths represent the range of strengths commonly used in flexural members. Three ranges of reinforcement ratio are investigated: 0.003 to 0.005, which is representative of two-way slabs; 0.006 to 0.010, which is representative of one-way slabs; and, 0.011 to 0.018, which is representative of beams. The reasons for selecting these three ranges are: they reflect typical reinforcement ratio ranges for slabs and beams; minimum and maximum reinforcement ratio limits are satisfactory in all cases; and, the upper limit of
the studied range of beams is defined by the maximum reinforcement ratio for a beam with $f_{c'}$ of 25 MPa. The same maximum reinforcement ratio is used for beams with $f_{c'}$ of 45 MPa. One layer of reinforcing steel is assumed.

2.3.2 Design Strength Ratios

Design flexural strength equations corresponding to the current ACI 318-14 and partial material strength reduction factors formats are defined in this section. The equations and definitions below refer to ACI 318-14, MacGregor and Bartlett (2000), and Wight (2016).

In ACI 318-14, the depth of the equivalent rectangular stress block, $a$, is computed as (Wight 2016)

$$a = \frac{A_s f_y}{0.85 f_{c'} b}$$  \[2.1\]

where: $A_s$ is the area of the nonprestressed longitudinal tension reinforcement; $f_y$ is the specified yield strength for nonprestressed reinforcement; $f_{c'}$ is the specified compressive strength of concrete; and, $b$ is the width of the compression face of the member. The design flexural strength, $\phi M_n$, is (Wight 2016)

$$\phi M_n = \phi A_s f_y \left( d - \frac{a}{2} \right)$$  \[2.2\]

where: $\phi$ is the strength reduction factor in ACI 318-14; $M_n$ is the nominal flexural strength at a section; and, $d$ is the distance from the extreme compression fiber to the centroid of the longitudinal tension reinforcement.

For the proposed method, the depth of the equivalent rectangular stress block, $a_r$, based on the partial material strength reduction factors format presented in MacGregor and Bartlett (2000), is assumed to be

$$a_r = \frac{\phi A_s f_y}{0.85 \phi f_{c'} b}$$  \[2.3\]
where: $\phi_r$ is the strength reduction factor for reinforcing steel; and, $\phi_c$ is the strength reduction factor for concrete. The design flexural strength for partial material strength reduction factors method, $M_r$, is (MacGregor and Bartlett 2000)

$$M_r = \phi_r A_r f_y \left( d - \frac{a_r}{2} \right) \quad \text{(2.4)}$$

For the longitudinal reinforcement ratio, $\rho$, defined as (ACI Committee 318 2014)

$$\rho = \frac{A_s}{bd} \quad \text{(2.5)}$$

the design flexural strength ratio, $\alpha_M$, is

$$\alpha_M = \frac{\phi M_n}{M_r} = \frac{\phi \left( 1 - \frac{\rho}{1.7} \cdot \frac{f_y}{f_c'} \right)}{\phi_s \left( 1 - \frac{\phi_s \rho}{1.7 \phi_c} \cdot \frac{f_y}{f_c'} \right)} \quad \text{(2.6)}$$

For each strength reduction factor combination, design flexural strength ratios, $\alpha_M$, were calculated with respect to longitudinal reinforcement ratios, $\rho$. Also, each calculation was done twice because two specified compressive strengths of concrete, $f_c'$, were studied. In particular, for $f_c'$ of 25 MPa, the strength reduction factors in ACI 318-14, $\phi$, are not always equal to 0.90 in the range of reinforcement ratios studied, e.g., $\phi$ is equal to 0.86 for $\rho$ of 0.017 and $\phi$ is equal to 0.83 for $\rho$ of 0.018. As mentioned in Chapter 1, when the section is tension-controlled, i.e. the net tensile strain in the extreme layer of longitudinal tension reinforcement at nominal strength, $\varepsilon_t$, is larger than or equal to 0.005, $\phi$ is equal to 0.90. Moreover, $\phi$ less than 0.90 implies that $\varepsilon_t$ is less than 0.005, but at least 0.004 (minimum requirement, used to control the upper limit of longitudinal reinforcement ratio) and the section is in the transition region between the tension-controlled and compression-controlled regions (ACI Committee 318 2014). The equation to compute the net tensile strain in the extreme layer of longitudinal tension reinforcement at nominal strength, $\varepsilon_t$, is (Wight 2016)
\[ \varepsilon_t = \left( \frac{d_t - c}{c} \right) \varepsilon_{cu} \]  

[2.7]

where: \( d_t \) is the distance from the extreme compression fiber to the extreme layer of tension steel; \( \varepsilon_{cu} \) is the maximum usable strain at the extreme concrete compression fiber, assumed equal to 0.003 in ACI 318-14; and, \( c \) is the distance from the extreme compression fiber to the neutral axis given by (ACI Committee 318 2014)

\[ c = \frac{a}{\beta_1} \]  

[2.8]

where \( \beta_1 \) is the factor relating the depth of the equivalent rectangular compressive stress block to the depth of the neutral axis. It is computed as (ACI Committee 318 2014)

For \( 17.5 \text{ MPa} \leq f_c' \leq 28 \text{ MPa}, \)

\[ \beta_1 = 0.85 \]  

[2.9]

For \( 28 \text{ MPa} < f_c' < 56 \text{ MPa}, \)

\[ \beta_1 = 0.85 - \frac{0.05(f_c' - 28)}{7} \]  

[2.10]

For \( f_c' \geq 56 \text{ MPa}, \)

\[ \beta_1 = 0.65 \]  

[2.11]

In this study, one layer of reinforcing steel is assumed, so \( d_t \) equals \( d \). From Equations [2.1], [2.7] and [2.8], \( \varepsilon_t \) can be computed as

\[ \varepsilon_t = 0.003 \times \frac{0.85\beta_1 f_c'}{\rho f_y} - 0.003 \]  

[2.12]

According to Equation [2.12], increasing the longitudinal reinforcement ratio, \( \rho \), reduces \( \varepsilon_t \), and when \( \varepsilon_t \) is less than 0.005, \( \phi \) also reduces. Similarly, when \( f_c' \) increases, \( \varepsilon_t \)
increases, so all of the $\phi$ values equal 0.90 for $f'_{c}$ of 45 MPa for the range of reinforcement ratios studied.

The relationships between the design flexural strength ratios, $\alpha_M$, and the longitudinal reinforcement ratios, $\rho$, for all ranges of reinforcement ratio are summarized in Figure 2.1 for $f'_{c}$ of 25 MPa and Figure 2.2 for $f'_{c}$ of 45 MPa. For each partial material strength reduction factor combination, when $\phi$ equals 0.90, $\alpha_M$ increases as $\rho$ increases. This occurs because the impact of $\phi_c$ on the lever arm between the resultant tension and compression forces increases as the reinforcement ratio and associated stress block depth increase. $\alpha_M$ decreases when $\phi$ is less than 0.90, because the gradual decrease of $\phi$ leads to the reduction of the design flexural strength in ACI 318-14, $\phi M_n$. In both figures, four families of trend lines correspond to the four $\phi_c$ values, while the differences within each family are defined by the four $\phi_s$ values. Therefore, the design flexural strength ratio, $\alpha_M$, is more sensitive to $\phi_s$ than to $\phi_c$. The influence of the reinforcement ratios is small when sections are in the tension-controlled region ($\phi$ of 0.90), but relatively large changes of $\alpha_M$ occur in the transition region. Comparing Figures 2.1 and 2.2, the influence of $f'_{c}$ is small, but $f'_{c}$ affects the dispersion of each family: the data are more concentrated for a given $\phi_s$ value when $f'_{c}$ is 45 MPa.

2.3.3 Recommended Partial Material Strength Reduction Factors

For $f'_{c}$ of 25 MPa, the means and standard deviations of $\alpha_M$ for the three ranges of longitudinal reinforcement ratio are summarized in Tables 2.2–2.4. Regardless of the reinforcement ratios, as $\phi_c$ increases from 0.60 to 0.75, the mean of $\alpha_M$ decreases and as $\phi_s$ increases from 0.80 to 0.95, the mean of $\alpha_M$ also reduces, but more markedly. This demonstrates $\alpha_M$ is more sensitive to $\phi_s$, because the design flexural strength is affected more by $\phi_s$ than by $\phi_c$. This is also evident from the results shown in Figure 2.1.

The standard deviation of $\alpha_M$, reduces for increased $\phi_c$ values for reinforcement ratios ranging from 0.003 to 0.005 and from 0.006 to 0.010, respectively. An opposite trend occurs for reinforcement ratios ranging from 0.011 to 0.018 because the strength reduction factor in ACI 318-14, $\phi$, is not always equal to 0.90, e.g., $\phi$ equals 0.86 for $\rho$ of
0.017 and \( \phi \) equals 0.83 for \( \rho \) of 0.018. This is evident in Figure 2.1: the slopes become flatter with the increase of \( \phi \), when \( \phi \) equals 0.90, so the variations of \( \alpha_M \) become smaller. When \( \phi \) increases, the standard deviation of \( \alpha_M \) increases for the first two reinforcement ratio ranges, but an opposite trend still occurs for reinforcement ratios ranging from 0.011 to 0.018.

The principle for selecting the best partial material strength reduction factors is to find the combinations where the mean design strength ratios approach 1 (or perhaps a value slightly larger than 1 to make the proposed design strengths slightly conservative) and the standard deviations are the least. When reinforcement ratios range from 0.003 to 0.005, the best combination is \( \phi_s \) of 0.90 and \( \phi_c \) of 0.75. When they range from 0.006 to 0.010, the best combination is again \( \phi_s \) of 0.90 and \( \phi_c \) of 0.75. And for beams with reinforcement ratios from 0.011 to 0.018, the best combination is \( \phi_s \) of 0.95 and \( \phi_c \) of 0.65, but the combination with \( \phi_s \) of 0.90 and \( \phi_c \) of 0.75 is nearly optimal. These also can be realized by inspection of Equation [2.6]: when \( \phi \) equals 0.90, \( \phi_s \) and \( \phi_c \) should be located on opposite sides of 0.90 to achieve the similar design strengths. Moreover, the design strength is more sensitive to \( \phi_s \) in the tension-controlled region, so if \( \phi_s \) equals 0.90, \( \phi_c \) should approach 0.90 and the closest value, 0.75, is the best. When the section is in the transition region, \( \phi \) reduces and the influence of the concrete strength increases, so \( \phi_c \) tends to reduce.

For \( f_c' \) of 45 MPa, the means and standard deviations of \( \alpha_M \) are summarized in Tables 2.5–2.7. The mean has the similar trend to that observed previously for \( f_c' \) of 25 MPa. The variation of the standard deviations, for all reinforcement ratio ranges is similar to that observed for \( f_c' \) of 25 MPa and reinforcement ratios ranging from 0.003 to 0.005 and from 0.006 to 0.010. The reason is that, for \( f_c' \) of 45MPa, the strength reduction factor in ACI 318-14, \( \phi \), is always equal to 0.90 in the range of reinforcement ratios studied. The best combination is therefore again \( \phi_s \) of 0.90 and \( \phi_c \) of 0.75.

In summary, if the section is tension-controlled with \( \phi \) of 0.90, the best partial material strength reduction factor combination is \( \phi_s \) of 0.90 and \( \phi_c \) of 0.75. If the section is in the
transition region between the tension-controlled and compression-controlled regions, the combination with $\phi_s$ of 0.95 and $\phi_c$ of 0.65 is the best. Actually, all of the combinations in the family with $\phi_s$ of 0.90 are potentially suitable. For lower $\phi_c$ values, although the standard deviations of $\alpha_M$ are larger, they also yield higher means.

2.4 One-way Shear

This section presents partial material strength reduction factors that most closely approximate the design shear strengths obtained using the ACI 318-14 criteria. The analysis process is similar to that previously presented for moment.

2.4.1 Geometric and Material Properties

The investigation of one-way shear is limited to rectangular beams designed in accordance with ACI 318-14 with stirrups perpendicular to the longitudinal axes of the beams. The specified yield strength of transverse reinforcement, $f_{ys}$, equals 420 MPa and the two grades of normalweight concrete represent the range of commonly used strengths, $f'_c$, of 25 and 45 MPa. The ranges of stirrup ratio, $\rho_t$, investigated are from 0.001 to 0.007 for $f'_c$ of 25 MPa and from 0.001 to 0.010 for $f'_c$ of 45 MPa. The selected ranges represent the ranges of minimum to maximum transverse reinforcement ratios permitted by ACI 318-14. Maximum stirrup spacing criteria are not always satisfied for some of the transverse reinforcement ratios, because the bar size is assumed fixed and the change of transverse reinforcement ratios is controlled by the spacing.

2.4.2 Design Strength Ratios

Design shear strength equations corresponding to the current ACI 318-14 and partial material strength reduction factors formats are defined in this section. The equations and definitions below refer to ACI 318-14, MacGregor and Bartlett (2000), and Wight (2016).

In ACI 318-14, for nonprestressed members without axial force, the nominal shear strength provided by concrete, $V_c$, is
\[ V_c = 0.17 \lambda \sqrt{f_c' b_w d} \]  \hspace{1cm} [2.13]

where: \( \lambda \) is the modification factor to account for the reduced shear strength of lightweight concrete, and equals 1.0 for normalweight concrete; and, \( b_w \) is the web width. The nominal shear strength provided by shear reinforcement, \( V_s \), is (ACI Committee 318 2014)

\[ V_s = \frac{A_v f_{sv} d}{s} \]  \hspace{1cm} [2.14]

where \( s, A_v \) and \( f_{sv} \) are the center-to-center spacing, the area within spacing \( s \), and the specified yield strength, respectively, of the transverse reinforcement. The design one-way shear strength at a cross section, \( \phi V_n \), is (ACI Committee 318 2014)

\[ \phi V_n = \phi (V_c + V_s) \]  \hspace{1cm} [2.15]

where \( V_n \) is the nominal one-way shear strength, and \( \phi \) equals 0.75 for members resisting shear.

For the proposed method, the design shear strength provided by concrete, \( V_{rc} \), based on the partial material strength reduction factors format presented in MacGregor and Bartlett (2000), is assumed to be

\[ V_{rc} = 0.17 \lambda \phi_c \sqrt{f_c' b_w d} \]  \hspace{1cm} [2.16]

The design shear strength provided by shear reinforcement, \( V_{rs} \), is (MacGregor and Bartlett 2000)

\[ V_{rs} = \frac{\phi_s A_v f_{sv} d}{s} \]  \hspace{1cm} [2.17]

The design one-way shear strength, \( V_r \), is therefore (MacGregor and Bartlett 2000)

\[ V_r = V_{rc} + V_{rs} \]  \hspace{1cm} [2.18]
For the transverse reinforcement ratio, \( \rho_t \), defined as (ACI Committee 318 2014)

\[
\rho_t = \frac{A_t}{b_n s}
\]  

[2.19]

the design shear strength ratio, \( \alpha_V \), is

\[
\alpha_V = \frac{\phi V_u}{V_r} = \frac{\phi \left( 0.17\lambda \sqrt{f'_c + \rho_t f_{ys}} \right)}{0.17\lambda \phi_c \sqrt{f'_c + \phi_s \rho_t f_{ys}}} \]  

[2.20]

For each partial material strength reduction factor combination, the design shear strength ratios, \( \alpha_V \), were calculated with respect to transverse reinforcement ratios, \( \rho_t \). Again, each calculation was conducted twice because two \( f'_c \) values were investigated.

The relationships between the design shear strength ratios, \( \alpha_V \), and the transverse reinforcement ratios, \( \rho_t \), are summarized in Figure 2.3 for \( f'_c \) of 25 MPa and Figure 2.4 for \( f'_c \) of 45 MPa. For each partial material strength reduction factor combination, the design shear strength ratio, \( \alpha_V \), declines as the transverse reinforcement ratio, \( \rho_t \), increases. However, the sensitivity of \( \alpha_V \) to \( \rho_t \) becomes small for increased \( \rho_t \). As for sections resisting moment, four families of trend lines correspond to the four \( \phi_c \) values, and the differences within each family are defined by the four \( \phi_s \) values. The four families overlap, however, so have been shown in separate figures. The variation of \( \alpha_V \) is greatest for low \( \rho_t \), low \( \phi_c \), and high \( \phi_s \): as \( \rho_t \) or \( \phi_c \) increases or \( \phi_s \) decreases, the sensitivities of \( \alpha_V \) to changes of these parameters reduce. Comparing Figures 2.3 and 2.4, the influence of \( f'_c \) on \( \alpha_V \) is small.

### 2.4.3 Recommended Partial Material Strength Reduction Factors

For \( f'_c \) of 25 MPa and \( \rho_t \) of 0.001–0.007, the means and standard deviations of \( \alpha_V \) are summarized in Table 2.8. As \( \phi_c \) increases from 0.60 to 0.75, the mean of \( \alpha_V \) decreases and as \( \phi_s \) increases from 0.80 to 0.95, the mean of \( \alpha_V \) also reduces. The magnitude of the proposed design shear strength is more sensitive to \( \phi_c \) than to \( \phi_s \), but the difference is less than that for flexural members. This is why the four families of trend lines defined for
each $\phi_s$ in Figure 2.3 tend to overlap. The standard deviation of $\alpha_V$ reduces for increased $\phi_c$ values, and increases for increased $\phi_s$ values. This is consistent with a previous observation concerning Figure 2.3: the variation of $\alpha_V$ is greatest for low $\phi_c$ and high $\phi_s$, because as $\phi_c$ increases or $\phi_s$ decreases, the sensitivities of $\alpha_V$ to these parameters reduce.

The best strength reduction factor combination has a mean design strength ratio approaching 1 with the least standard deviation. The best partial material strength reduction factor combination is $\phi_s$ of 0.80 and $\phi_c$ of 0.65. Moreover, combinations with $\phi_s$ of 0.80 and $\phi_c$ of 0.70, and $\phi_s$ of 0.85 and $\phi_c$ of 0.60 are close to optimal. These also can be realized by inspection of Equation [2.20]: when $\phi$ equals 0.75, $\phi_s$ and $\phi_c$ should be located on opposite sides of 0.75 to achieve the similar design strengths.

For $f_{c'}$ of 45 MPa, the means and standard deviations are summarized in Table 2.9. The values have the similar trends to those discussed previously for $f_{c'}$ of 25 MPa. The best partial material strength reduction factor combination remains $\phi_s$ of 0.80 and $\phi_c$ of 0.65. Again, combinations with $\phi_s$ of 0.80 and $\phi_c$ of 0.70, and $\phi_s$ of 0.85 and $\phi_c$ of 0.60 are close to optimal.

2.5 Combined Moment and Axial Force

This section proposes partial material strength reduction factors that most closely approximate the combined flexural and axial strengths obtained using the ACI 318-14 design criteria. The analysis process is similar to those previously presented for moment and shear. Five column cross sections and eight property combinations for each cross section are investigated. The ratios of the design strengths corresponding to ACI 318-14 to those corresponding to various combinations of partial material strength reduction factors are calculated with respect to specific $e/h$ (eccentricity/overall column depth) values.

2.5.1 Geometric and Material Properties

The investigation of combined moment and axial force is limited to the following five column cross sections, as shown in Figure 2.5:
1. Square section with three bars in each face.
2. Square section with three bars in two end faces only.
3. Square section with three bars in two side faces only.
4. Tied circular section with eight bars evenly distributed around the perimeter.
5. Spirally reinforced circular section with eight bars evenly distributed around the perimeter.

In all cases, the bending is assumed applied about a horizontal axis, $x-x$.

For each cross section, eight property combinations designed based on ACI 318-14 shown in Table 2.10 are investigated to account for varying steel location, steel area, and concrete strength. The values of $\gamma$, the ratios of the distance between the outer layers of reinforcement to the overall column depth, of 0.6 and 0.9 are considered as they bound commonly used values. The widths and overall depths corresponding to these two $\gamma$ values are 325 and 1300 mm, respectively, to achieve a 65 mm distance from the outer reinforcement layer to the adjacent column face. Total reinforcement ratios, $\rho_g$, of 0.01 and 0.04 are investigated because these are the lower and upper limits, respectively, in columns containing lap splices (ACI Committee 318 2014). Specified concrete compressive strengths, $f'_c$, of 25 and 45 MPa are investigated. In all cases, the reinforcement yield strength, $f_y$, equals 420 MPa. These material strengths are identical to those investigated previously for moment and shear.

### 2.5.2 Design Strength Ratios

Design combined flexural and axial strength equations corresponding to the current ACI 318-14 and partial material strength reduction factors formats are defined in this section. The equations and definitions below refer to ACI 318-14, MacGregor and Bartlett (2000), and Wight (2016).

Setting the strain in the extreme tension layer of steel, $\varepsilon_{s1}$, equal to $Z\varepsilon_y$, where $\varepsilon_y$ is the yield strain of reinforcement, and $Z$ is the ratio of the strain in the extreme tension layer of steel to the yield strain, the distance from the extreme compression fiber to the neutral axis, $c$, is (Wight 2016)
\[ c = \left( \frac{0.003}{0.003 - Z_{e_y}} \right) d_i \]  \hspace{1cm} [2.21]

where \( d_i \) is the distance from the extreme compression fiber to the reinforcement located furthest from the extreme compression fiber. The depth of the equivalent rectangular stress block, \( a \), is computed as (Wight 2016)

\[ a = \beta_i c \]  \hspace{1cm} [2.22]

and must not be greater than the section depth, \( h \). The strain in the \( i \)th layer of reinforcement, \( \varepsilon_{si} \), is (Wight 2016)

\[ \varepsilon_{si} = \left( \frac{c - d_i}{c} \right) 0.003 \]  \hspace{1cm} [2.23]

where \( d_i \) is the distance from the extreme compression fiber to the \( i \)th layer of reinforcement. Tensile strains, stresses and forces are taken to be negative quantities. The stress in the \( i \)th layer of reinforcement, \( f_{si} \), is (Wight 2016)

\[ f_{si} = \varepsilon_{si} E_s \text{ but } -f_y \leq f_{si} \leq f_y \]  \hspace{1cm} [2.24]

where \( E_s \) is the modulus of elasticity of reinforcement.

In ACI 318-14, the nominal compressive force in concrete, \( C_c \), is (Wight 2016)

\[ C_c = 0.85 f'_{cb} \]  \hspace{1cm} [2.25]

If \( a \) is less than \( d_i \), the nominal force in the \( i \)th layer of reinforcement, \( F_{si} \), is (Wight 2016)

\[ F_{si} = f_{si} A_{si} \]  \hspace{1cm} [2.26]

where \( A_{si} \) is the area of the \( i \)th layer of reinforcement. If \( a \) is greater than \( d_i \), it is necessary to account for the concrete displaced by the steel (Wight 2016):

\[ F_{si} = (f_{si} - 0.85 f'_{cb}) A_{si} \]  \hspace{1cm} [2.27]
The design axial strength, $\phi P_n$, is (Wight 2016)

$$\phi P_n = \phi \left( C_c + \sum_{i=1}^{n} F_{si} \right)$$ \hspace{1cm} [2.28]

where $P_n$ is the nominal axial strength of a member.

The design flexural strength, $\phi M_n$, is (Wight 2016)

$$\phi M_n = \phi \left( C_c \left( \frac{h}{2} - \frac{a}{2} \right) + \sum_{i=1}^{n} F_{si} \left( \frac{h}{2} - d_i \right) \right)$$ \hspace{1cm} [2.29]

To account for accidental eccentricities, the maximum design axial compressive strength, $\phi P_{n,max}$, for tied columns is (Wight 2016)

$$\phi P_{n,max} = 0.80\phi \left( 0.85 f'c \left( A_g - A_{st} \right) + f_y A_{st} \right)$$ \hspace{1cm} [2.30]

and for spirally reinforced columns is (Wight 2016)

$$\phi P_{n,max} = 0.85\phi \left( 0.85 f'c \left( A_g - A_{st} \right) + f_y A_{st} \right)$$ \hspace{1cm} [2.31]

where: $P_{n,max}$ is the maximum nominal axial compressive strength of a member; $A_g$ is the gross area of the section; and, $A_{st}$ is the total area of the nonprestressed longitudinal reinforcement. The design axial tensile strength, $\phi P_{nt}$, is (Wight 2016)

$$\phi P_{nt} = -\phi f_y A_{st}$$ \hspace{1cm} [2.32]

where $P_{nt}$ is the nominal axial tensile strength of a member.

For the proposed method, the factored compressive force in concrete, $C_{rc}$, based on the partial material strength reduction factors format presented in MacGregor and Bartlett (2000), is assumed to be

$$C_{rc} = 0.85\phi f'c ab$$ \hspace{1cm} [2.33]
If \( a \) is less than \( d_i \), the factored force in the \( i \)th layer of reinforcement, \( F_{rsi} \), is (MacGregor and Bartlett 2000)

\[
F_{rsi} = \phi_c f_{si} A_{si}
\]  

(2.34)

If \( a \) is greater than \( d_i \), it is assumed to be (MacGregor and Bartlett 2000)

\[
F_{rsi} = (\phi_c f_{si} - 0.85\phi_c f_c') A_{si}
\]  

(2.35)

The design axial strength, \( P_r \), is (MacGregor and Bartlett 2000)

\[
P_r = C_{rc} + \sum_{i=1}^{n} F_{rsi}
\]  

(2.36)

The design flexural strength, \( M_r \), is (MacGregor and Bartlett 2000)

\[
M_r = C_{rc} \left( \frac{h}{2} - \frac{a}{2} \right) + \sum_{i=1}^{n} F_{rsi} \left( \frac{h}{2} - d_i \right)
\]  

(2.37)

To account for accidental eccentricities, the maximum design axial compressive strength, \( P_{r,\text{max}} \), for tied columns is assumed to be (MacGregor and Bartlett 2000)

\[
P_{r,\text{max}} = 0.80 \left( 0.85\phi_c f_c' (A_g - A_{si}) + \phi_c f_{si} A_{si} \right)
\]  

(2.38)

and for spirally reinforced columns is assumed to be (MacGregor and Bartlett 2000)

\[
P_{r,\text{max}} = 0.85 \left( 0.85\phi_c f_c' (A_g - A_{si}) + \phi_c f_{si} A_{si} \right)
\]  

(2.39)

The design axial tensile strength, \( P_t \), is (MacGregor and Bartlett 2000)

\[
P_t = -\phi_c f_{si} A_{si}
\]  

(2.40)

The design eccentricity for ACI 318-14, \( e_u \), equals \( \phi M_p/\phi P_n \), and for the proposed method, \( e_r \), equals \( M_d/P_r \). For a specific value of \( elh \), ratio \( \alpha_{PM} \), of design combined
flexural and axial strengths computed using the strength reduction factor in ACI 318-14 and the partial material strength reduction factors is (Hong and Zhou 1999)

\[
\alpha_{PM} = \left( \frac{\phi P_n}{\sqrt{P_n^2 + \left( \frac{M_n}{h} \right)^2}} \right) \left( \frac{\phi M_n}{h} \right) = \frac{\phi P_n}{\sqrt{1 + \left( \frac{e_n}{h} \right)^2}}
\]

Values of \( \alpha_{PM} \) greater than 1 represent cases where the design strengths computed using the current ACI 318-14 criteria exceed, and are therefore unconservative with respect to, those computed using the partial material strength reduction factors criteria.

For circular columns, the strain-compatibility solution described above can also be used. The only differences are the area of the compression segment of the circular section, \( A \), and the moment of this area about the center of the column, \( A\bar{y} \), which are (Wight 2016)

\[
A = h^2 \left( \frac{\theta - \sin \theta \cos \theta}{4} \right)
\]

\[
A\bar{y} = h^3 \left( \frac{\sin^3 \theta}{12} \right)
\]

where angle \( \theta \), defined in Figure 2.6 (which is similar to Fig. 11–20 in Wight (2016)), is expressed in radians. If \( a \leq h/2 \), which corresponds to \( \theta \leq \pi/2 \) (Wight 2016),

\[
\theta = \cos^{-1} \left( \frac{h/2 - a}{h/2} \right)
\]

If \( a > h/2 \), which corresponds to \( \theta > \pi/2 \) (Wight 2016),

\[
\theta = \pi - \cos^{-1} \left( \frac{a - h/2}{h/2} \right)
\]

To compare design strengths for ACI 318-14 and the proposed method, the calculation of \( \alpha_{PM} \) is based on identical \( e_{ud}/h \) and \( e_i/h \) values of 0 (compression only), 0.1, 0.2, 0.3, 0.4,
0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0, 9.0, 10.0, −10.0, −5.0, −1.0, −0.5, −0.1 and 0 (tension only). Interpolation in Matlab (Version R2016b; The Mathworks, Inc. 2016) was used to obtain $\phi P_n$, $P_r$ and $\alpha_{PM}$ values corresponding to these specific $e/h$ values. The Matlab (Version R2016b; The Mathworks, Inc. 2016) codes for Column Section 1 (square section with three bars in each face) and Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), two representative cross sections, are presented in Appendix A.

For Column Section 1 (square section with three bars in each face), the relationships between $\alpha_{PM}$, and the specific $e/h$ for Property Combination 1 ($\gamma$ of 0.6, $f'_c$ of 25 MPa, and $\rho_s$ of 0.01) are shown in Figure 2.7a for $e/h > 0$. The dotted vertical line on the figure shows $e_{uball}/h$ of 0.42, where $e$ corresponds to the balanced failure for ACI 318-14. The solid vertical lines show the range of $e$ values corresponding to the balanced failures for the sixteen partial material strength reduction factor combinations, from $(e_{rball}/h)_{min}$ of 0.43 to $(e_{rball}/h)_{max}$ of 0.50. The horizontal axis has a log scale to separate the data corresponding to the lower $e/h$ values, which are the most common cases in short columns. When $e/h > 0$, for each partial material strength reduction factor combination, $\alpha_{PM}$ reduces as $e/h$ increases until the balance point is reached. The large increase of $\alpha_{PM}$ between $e/h \approx 0.4$ and $e/h \approx 0.8$ is due to the increase of $\phi$ in ACI 318-14 from 0.65 to 0.90. As the eccentricity increases, columns tend to be tension-controlled and $\alpha_{PM}$ declines slightly to a stable level. In the compression-controlled region, four distinct families of the lines correspond to the four $\phi_c$ values, and the slight differences within each family are defined by the four $\phi_s$ values, which indicates the significance of the concrete strength. As the eccentricity increases, the steel strength becomes more influential so the four families of the lines are defined by the four $\phi_s$ values, and the differences within each family are defined by the four $\phi_s$ values.

When $e/h < 0$, Figure 2.7b shows that $\alpha_{PM}$ increases slightly as the absolute value of $e/h$ increases. For the cross sections subjected to tension, the trend lines are also much more dependent on $\phi_s$, because the tensile strength of concrete is ignored. Figures
corresponding to the other property combinations are shown in Figures A.1–A.7 of Appendix A.

Figures 2.8a and 2.8b show $\alpha_{PM}$ values for the eight property combinations for Column Section 1 (square section with three bars in each face) for $el/h > 0$ and $el/h < 0$, respectively. The partial material strength reduction factors correspond to $\phi_s$ of 0.90 and $\phi_c$ of 0.60. For $el/h$ approximately ranging from 0.1 to 0.38, all of the eight property combinations for both of the ACI 318-14 and partial material strength reduction factors criteria do not reach the minimum value of $e_{uball}/h$ or $e_{rbal}/h$, so they are compression-controlled. In this region, the influence of $\gamma$ is very small, because of the small applied eccentricity. The influence of $f'_{c}$ is moderate, but $\rho_s$ makes a big difference. For $el/h$ approximately ranging from 0.38 to 1.3, some reach the balance point, but others do not. For $el/h$ approximately ranging from 1.3 to 10, all of the eight property combinations for both of the ACI 318-14 and partial material strength reduction factors criteria equal or exceed the maximum value of $e_{uball}/h$ or $e_{rbal}/h$, so they are in the transition or tension-controlled regions. The two lines corresponding to Property Combination 2 ($\gamma$ of 0.6, $f'_{c}$ of 25 MPa, and $\rho_s$ of 0.04) and Property Combination 4 ($\gamma$ of 0.6, $f'_{c}$ of 45 MPa, and $\rho_s$ of 0.04), differ from the others shown because they remain in the transition region until $el/h$ equals 10: in other words, $\varepsilon_t$ equal to 0.005 occurs when $el/h \geq 10$. For $el/h$ less than 0, the sections are subjected to tension. In the tension-controlled region, with the increase of $el/h$, $\gamma$ tends to become more significant, and followed by $\rho_s$ and $f'_{c}$.

For Column Sections 2, 3 and 4, the $\alpha_{PM}$ values are similar to those for Column Section 1. The results are shown in Figures A.8–A.31 of Appendix A. For Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), the relationships between $\alpha_{PM}$, and the specific $el/h$ for Property Combination 1 ($\gamma$ of 0.6, $f'_{c}$ of 25 MPa, and $\rho_s$ of 0.01) are shown in Figures 2.9a and 2.9b, for $el/h > 0$ and $el/h < 0$, respectively. In the compression-controlled region, $\alpha_{PM}$ increases markedly compared to the values for the tied columns, because $\phi$ in ACI 318-14 for spirally reinforced columns equals 0.75 instead of 0.65. Figures corresponding to the other property combinations are shown in Figures A.32–A.38.
2.5.3  Recommended Partial Material Strength Reduction Factors

For Column Section 1 (square section with three bars in each face), the minimum and maximum values of $e/h$ for all eight property combinations corresponding to the ACI 318-14 and partial material strength reduction factors criteria at the balance point are 0.383 and 1.361, respectively. It is therefore decided to categorize the data in four $e/h$ ranges: (1) $0 \leq e/h \leq 0.3$, corresponding to compression-controlled failures; (2) $0.3 < e/h \leq 1.0$, an intermediate range; (3) $1.0 < e/h \leq 10.0$, corresponding to data below the balanced point on interaction diagrams, in the tension-controlled region or the transition region; and, (4) $e/h \leq 0$, corresponding to axial tension. For the eight property combinations, the means and standard deviations of $\alpha_{PM}$ are summarized in Tables 2.11–2.14. As $\phi_c$ increases from 0.60 to 0.75, the mean of $\alpha_{PM}$ decreases. Similarly as $\phi_s$ increases from 0.80 to 0.95, the mean of $\alpha_{PM}$ also decreases. The magnitude of the design strength ratio is more sensitive to $\phi_c$ than to $\phi_s$ in Range (1), the compression-controlled region, as shown in Table 2.11, while the reverse happens in Ranges (3) and (4), as shown in Tables 2.13 and 2.14. All the means are less than 1 in the compression-controlled region, indicating any of the partial material strength reduction factor combination considered yields higher design strengths and so is less conservative compared with ACI 318-14. The standard deviation of $\alpha_{PM}$ reduces with increased $\phi_c$ values and increases with increased $\phi_s$ values in Ranges (1) and (4). In Ranges (2) and (3), the standard deviation of $\alpha_{PM}$ decreases with increased $\phi_s$ and $\phi_c$.

The best partial material strength reduction factor combination corresponds to that having a mean design strength ratio approaching 1 with the least standard deviation. In the compression-controlled region, the family of partial material strength reduction factors with $\phi_c$ of 0.60 is the best and, at greater eccentricities, the family of partial material strength reduction factors with $\phi_s$ of 0.90 is the best. To further investigate which combination of partial material strength reduction factors is appropriate, reliability analyses will be presented in Chapter 4.
For Column Sections 2, 3 and 4, the results are similar to Column Section 1 and the results are shown in Tables A.1–A.12 of Appendix A. And the boundary for $el/h$ between Ranges (1) and (2) is 0.4 for Column Section 2.

For Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), the results are shown in Tables 2.15–2.18: In the compression-controlled region, the family of partial material strength reduction factors with $\phi_r$ of 0.70 is the best and, at greater eccentricities, both the families with $\phi_r$ of 0.90 and 0.95 are the best. Alternatively an overall factor could be applied to the factored resistance of spirally reinforced columns to account for the advantage of confinement. The magnitude of this factor should be between $(0.75/0.65 =) 1.15$ and $(0.90/0.90 =) 1$. However, if a single overall factor is adopted, the associated best partial material strength reduction factors for the compression-controlled and tension-controlled regions will be different. As the different $\phi$ factors for tied and spirally reinforced columns in ACI 318-14 impact mostly the region of compression-controlled failure, it may be better to apply a unique $\phi_c$ value to spirally reinforced columns. To further investigate which combination of partial material strength reduction factors is appropriate, reliability analyses will be presented in Chapter 4.

### 2.6 Summary and Conclusions

This chapter has presented the calculation of design strength ratios for cross sections subjected to moment, one-way shear, and combined moment and axial force. The best partial material strength reduction factors that best duplicate the design strengths obtained using the current ACI 318-14 provisions are proposed. The geometric and material properties of the designed sections represent commonly used values and meet most of the requirements in ACI 318-14. The preliminary results obtained in this chapter will be referred for reliability analyses presented in Chapters 3 and 4.

For members subjected to moment, the best partial material strength reduction factor combination is $\phi_r$ of 0.90 and $\phi_c$ of 0.75 if the section is tension-controlled. If the section is in the transition region between the tension-controlled and compression-controlled regions, the combination with $\phi_r$ of 0.95 and $\phi_c$ of 0.65 is the best, but the $\phi_r$ of 0.95 is an
extreme value, so maybe not satisfactory for reliability analyses. Actually, all of the combinations in the family with $\phi_\text{s}$ of 0.90 are potentially suitable. For lower $\phi_c$ values, although the standard deviations of $\alpha_M$ are larger, they also yield higher means.

For members resisting one-way shear, the best strength reduction factor combination is $\phi_\text{s}$ of 0.80 and $\phi_c$ of 0.65. Combinations with $\phi_\text{s}$ of 0.80 and $\phi_c$ of 0.70, and $\phi_\text{s}$ of 0.85 and $\phi_c$ of 0.60 are close to optimal. These results are only based on the design strength calculations, so they just duplicate the design strengths corresponding to ACI 318-14. As mentioned in Chapter 1, however, for members subjected to shear, the statistical parameters for the professional factor have changed significantly, so the reliability indices may be unsuitable for both ACI 318-14 and the partial material strength reduction factors, and lead to different preferred partial material strength reduction factors.

For members resisting combined moment and axial force, $\phi_\text{s}$ of 0.90 is the best for the tension-controlled region and $\phi_c$ of 0.60 is the best for the compression-controlled region for tied columns. For spirally reinforced columns, $\phi_c$ of 0.70 is preferred and both the families with $\phi_c$ of 0.90 and 0.95 seem reasonable.

The results obtained in this chapter are only based on the design strengths. However, if the reliability indices for the current ACI 318-14 criteria are not suitable, the reliability indices for the partial material strength reduction factors just duplicating the design strengths of the current criteria may be also unsatisfactory. In that case, the results obtained in this chapter will be less useful and the best partial material strength reduction factors will be determined only based on the reliability analyses.

Therefore, the final selection of the best partial material strength reduction factors will be made based on the reliability analyses presented in Chapters 3 and 4.

Chapter 3

3 Derivation of Partial Material Strength Reduction Factors for Moment or One-way Shear Based on Reliability Indices

3.1 Introduction

In Chapter 2, the partial material strength reduction factor combinations were recommended for moment, one-way shear, and combined moment and axial force based on similar design strengths obtained using ACI 318-14 (ACI Committee 318 2014) and the partial material strength reduction factors method. This simple calibration to the ACI 318-14 design strength criteria may not give the best results, however, if the ACI 318-14 criteria yield unsatisfactory reliabilities. This chapter presents the probability-based analyses to obtain reliability indices for moment and one-way shear based on ACI 318-14 and the proposed method. The range of geometric and material properties investigated are identical to those presented in Chapter 2.

The objective of this chapter is to determine appropriate partial material strength reduction factor combinations that approximate reliability indices obtained using the current ACI 318-14 provisions. A second objective is to quantify the ranges of reliability.

3.2 Methodology

Microsoft Excel (Version 2013; Microsoft 2013) is used to compute the reliability indices. The first-order, second-moment (FOSM) method is applied for simply supported members resisting moment or one-way shear. Statistical parameters to quantify the resistances and load effects are obtained from the literature. For the investigation presented in this chapter, the best combination of partial material strength reduction factors will give reliability indices that most closely approximate those obtained using the current ACI 318-14 provisions, if the range of reliability indices corresponding to ACI 318-14 is satisfactory. However, if the range of reliability indices is unsuitable, correction will be applied.
3.2.1 Reliability Model

The limit state function, $Z$, also denoted as $g(\bullet)$, related to the resistance, $R$, and the load effect, $Q$, is defined as (e.g., Ellingwood et al. 1980)

$$Z = g(R, Q) = \frac{R}{Q} \quad [3.1]$$

Failure corresponds to $Z < 1$ or $\ln Z < 0$.

The resistance is assumed to be represented by the following product model originally proposed by Galambos and Ravindra (1977):

$$R = GMP \quad [3.2]$$

where: $G$ is a geometric property; $M$ is a material strength property; and, $P$ is the professional factor.

The load effect for the $i$th type load, $Q_i$, quantifies the structural demand and is expressed as (Ellingwood et al. 1980)

$$Q_i = c_i B_i A_i \quad [3.3]$$

where: $c_i$ is an influence coefficient; $B_i$ is a modelling parameter; and, $A_i$ is the structural load itself. Ellingwood et al. (1980) assumed that “the transformation from load to load effect is linear, and $c_i$, $B_i$ and $A_i$ are statistically independent.” $B_i$ accounts for “the load model which transforms the actual spatially and temporally varying load into a statically equivalent uniformly distributed load”, and $c_i$ reflects “the analysis which transforms the equivalent uniformly distributed load to a load effect”.

For the limit state function defined by Equation [3.1], the first-order, second-moment reliability index, $\beta$, can be computed as (e.g., Ellingwood et al. 1980)

$$\beta = \frac{\ln\left(\frac{\bar{R}}{\bar{Q}}\right)}{\sqrt{V_R^2 + V_Q^2}} \quad [3.4]$$
where: $\bar{R}$ is the mean resistance; $\bar{Q}$ is the mean load effect; $V_R$ is the coefficient of variation of the resistance; and, $V_Q$ is the coefficient of variation of the load effect. To determine $\beta$, these four values must be calculated first before the reliability index can be computed.

### 3.2.2 Determination of Statistical Parameters for Resistance and Load Effect

The reliability analyses for members resisting moment or shear are based on the Taylor Series expansion to compute the resistance and load effect statistical parameters. This method is described by Ellingwood et al. (1980). The general form of the resistance or the load effect is

$$ R\{\text{or } Q\} = f(X_1, X_2, \ldots, X_n) $$

where $f(\bullet)$ is the function of resistance or load effect in the limit state function, and $X_i$ is the resistance or load variable, characterized by its first and second moments. The resistance and the load effect must be linearized at some point for the reliability analysis. The linearization, based on the Taylor Series expansion is (Ellingwood et al. 1980)

$$ R\{\text{or } Q\} \approx f\left(X_1^*, X_2^*, \ldots, X_n^*\right) + \sum \left(X_i - X_i^*\right) \frac{\partial f}{\partial X_i} \bigg|_{x^*} $$

where $\left(X_1^*, X_2^*, \ldots, X_n^*\right)$ is the linearizing point, taken as the means of the variables in this study. In other words, $\left(X_1^*, X_2^*, \ldots, X_n^*\right) = (\bar{X}_1, \bar{X}_2, \ldots, \bar{X}_n)$. Assuming the variables are statistically independent, the mean and standard deviation of $R$ or $Q$, $\bar{R}$ or $\bar{Q}$, and $\sigma_R$ or $\sigma_Q$, respectively, are approximated by (Ellingwood et al. 1980)

$$ \bar{R}\{\text{or } \bar{Q}\} \approx f\left(\bar{X}_1, \bar{X}_2, \ldots, \bar{X}_n\right) $$

$$ \sigma_R\{\text{or } \sigma_Q\} \approx \left[ \sum \left(\frac{\partial f}{\partial X_i} \bigg|_{x^*}\right)^2 \sigma_{X_i}^2 \right]^{1/2} $$
where $\bar{X}_i$ and $\sigma_{X_i}$ are the mean and standard deviation of the resistance or load variable, respectively.

3.3 Statistical Parameters

This section presents the statistical parameters obtained from the literature for use in the reliability analyses.

3.3.1 Geometric Properties

The geometric properties include the width, $b$, and the height, $h$, of the concrete cross section, the effective depth, $d$, of the flexural reinforcement and the area of the reinforcement, $A_s$. Table B.1 in Appendix B summarizes the absolute values, means and standard deviations, $\sigma$, for concrete geometric properties reported in the literature. They are due to measurement errors in the construction process and are controlled by specified tolerances and so are absolute values in mm. Table 3.1 shows the values used in this study selected from Table B.1. The statistical parameters for $b$ value for beams and $b$ and $h$ values for columns used in this study are derived from Ellingwood et al. (1980) and Mirza and MacGregor (1979). The standard deviation of $d$ is assumed to be 1/2 of the tolerance specified in Table 26.6.2.1a in ACI 318-14: this is consistent with the common approximation that the total tolerance range equals four standard deviations. The bias coefficient, $\delta$, and coefficient of variation, $V$, for the area of the reinforcement, $A_s$, is obtained from Nowak and Szerszen (2003).

3.3.2 Material Strengths

The equation used by Bartlett (2007) to characterize the concrete compressive strength is:

$$M = \frac{f_{c,i-p}}{f_c'} = F_1 F_2 F_{i-p} F_r$$

[3.9]

where: $f_{c,i-p}$ is the in-place compressive strength of the concrete; $f_c'$ is the 28-day specified strength; $F_1$ is a parameter representing the ratio of the mean 28-day control cylinder strength to the specified 28-day strength; $F_2$ is the ratio of the mean in-place strength at 28 days to the mean 28-day cylinder strength; $F_{i-p}$ accounts for the variation of the in-
place strength; and, $F_r$ accounts for rate-of-loading effects (Bartlett 2007). It is assumed that $F_1$, $F_2$, $F_{i,p}$ and $F_r$ are statistically independent.

The statistical parameters for $F_1$, $F_2$, $F_{i,p}$ obtained from the literature are shown in Table B.2–B.4 and the corresponding demonstration is also presented in Appendix B. Table B.5 shows statistical parameters for in-situ concrete compressive strength reported by Ellingwood et al. (1980). A summary of the statistical parameters for cast-in-place concrete used in the present study is shown in Table 3.2. Bartlett (2007) computed $F_r$ as 0.88 for dead plus live load combination for $f'_c$ from 20 to 35 MPa with assumption of 1 hour loading duration for live loads. The coefficients of variation for $F_1$, $F_2$ and $F_{i,p}$ are relatively large compared to $F_r$, so the coefficient of variation for $F_r$ is ignored (Bartlett 2007). The resulting statistical parameters for concrete compressive strength, adopted in the present study are a bias coefficient of 1.15 and a coefficient of variation of 0.211.

Table B.6 shows statistical parameters for reinforcement with yield strength, $f_y$, of 420 MPa. Nowak and Szerszen (2003) recommended a bias coefficient of 1.145 and a coefficient of variation of 0.05, which implies better control of yield strength than that reported by Ellingwood et al. (1980). The statistical parameters, a bias coefficient of 1.125 and a coefficient of variation of 0.098, reported by Ellingwood et al. (1980) have been adopted for the present study, because they are more conservative.

### 3.3.3 Professional Factors

Table 3.3 presents statistical parameters for professional factors from several sources. Somo and Hong (2006) explored the professional factor for shear strength based on 1146 beam tests reported in the literature. They categorized the results by the presence of stirrups and shear span-to-depth ratios, $a_i/d$. Their dataset includes data from Kani et al. (1979) for shallow beams tested at a very young age. Therefore, Somo and Hong (2006) also reanalyzed a reduced dataset that excludes Kani’s beam tests. Collins (2001) studied the professional factor for shear based on two datasets: one containing 776 beam tests and the other 413 beam tests. The larger dataset contains a much higher proportion of beams with depths less than 350 mm, more prestressed beams, and more beams without stirrups. In addition, at least 98% of the data in each dataset are for beams subjected to point
loads, whereas in practice, in buildings, it is more common to have beams subjected to uniformly distributed loads (Collins 2001). In a previous calibration of the ACI strength reduction factors, values of 1.09 and 0.12 were adopted by Israel et al. (1987).

Nowak and Szerszen (2003) investigated the bias coefficients and coefficients of variation for different structural members combining results reported by Ellingwood et al. (1980) with “engineering judgement”.

In the present investigation, for beams subjected to shear, beams with stirrups and shear span-to-depth ratios, \(a_v/d\), greater than 2 are of interest, so a bias coefficient of 1.47 and a coefficient of variation of 0.36 reported by Somo and Hong (2006) are used. For members subjected to other structural actions, statistical parameters presented by Nowak and Szerszen (2003) are used.

### 3.3.4 Load Effects

Based on Table 5.3.1 in ACI 318-14, the load combination investigated is:

\[
U = 1.2D + 1.6L
\]  

[3.10]

where: \(U\) is the required strength computed using the factored load combinations; \(D\) is the effect of the service dead load; and, \(L\) is the effect of the service live load.

The statistical parameters pertaining to the dead load effect and the 50-year maximum live load effect are shown in Table 3.4. For dead load, Ellingwood et al. (1980) assumed all construction materials have the same bias coefficients and coefficients of variation. Szerszen and Nowak (2003) concluded that the statistical parameters for cast-in-place and precast members were similar as shown. A bias coefficient of 1.05 and a coefficient of variation of 0.10 reported by Ellingwood et al. (1980) have been used in this study.

For live load, Table 3.4 shows that Israel et al. (1987) assumed a bias coefficient of 1.00 and a coefficient of variation of 0.25 when A58.1-1982 (ANSI 1982) live load reductions were used and these values are used in this study. Szerszen and Nowak (2003) and Bartlett et al. (2003) selected different parameters based on their literature review and assumptions, as shown. In particular, Bartlett et al. (2003) accounted for the
transformation from the load to the load effect separately which is the impact of the influence coefficient, $c_i$, and the modeling parameter, $B_i$, shown in Equation [3.3]. Denote the transformations from the dead load and live load to the dead load and live load effect by $T_D$ and $T_L$, respectively. In contrast, this transformation is already included in the live load effects reported by Israel et al. (1987), and Szerszen and Nowak (2003). In these cases, $T_L$ has a bias coefficient of 1.0 and a coefficient of variation of 0. The parameters reported by Bartlett et al. (2003) are based on the 1995 NBCC (NRCC 1995) live load reduction factors, so they are not suitable for the calibration in this study. The parameters reported by Israel et al. (1987) have been used.

3.4 Moment

This section presents reliability indices for moment derived using the partial material strength reduction factors for comparison with those computed based on the ACI 318-14 criteria. The design of the three cross sections representative of two-way slabs, one-way slabs and beams are quantified and assumptions applied in analyses are presented. The means and standard deviations of the reliability indices are quantified. The sensitivities of the reliability indices to the partial material strength reduction factor combinations for various geometric and material properties are investigated. The best factor combinations are recommended. The factor combinations deemed “best” not only give reliability indices that are similar to those obtained using the ACI 318-14 strength reduction factors but also yield acceptable absolute reliability index values. In other words, if the reliability indices corresponding to the ACI 318-14 strength reduction factors are excessively high or low, partial material strength reduction factor combinations are proposed that yield more satisfactory values.

3.4.1 Assumptions and Design Criteria

The reliability analysis of moment is based on the first-order, second-moment (FOSM) method (Ellingwood et al. 1980). Nominal values of geometric properties, material strengths and live-to-dead load ratios are selected that simulate practical values and are consistent with the requirements in ACI 318-14, as shown in Table 3.5. The design of the rectangular singly reinforced sections is based on Equations [2.1] to [2.5], reinforcement
limits, minimum thickness limits, specified concrete cover requirements and material strength requirements specified in ACI 318-14. The ranges of reinforcement ratio investigated are consistent with those in Chapter 2, specifically 0.003 to 0.005 for two-way slabs, 0.006 to 0.010 for one-way slabs and 0.011 to 0.018 for beams. The material strengths also correspond to those investigated in Chapter 2 with $f'_{c}$ of 25 or 45 MPa and $f_{y}$ of 420 MPa.

The typical specified live-to-dead load ratio, $w_{L}/w_{D}$, for flexural members ranges from 0.5 to 1.5 (Ellingwood et al. 1980), so the present study investigates ratios within this range. The specified dead and live loads are determined to exactly achieve the design flexural strength, $\phi M_{n}$ or $M_{r}$. Live load reduction factors due to tributary area are neglected. If they are considered, the range of typical $w_{L}/w_{D}$ ratios reduces slightly, but the reliability indices computed for a specific $w_{L}/w_{D}$ value are correct. Simply supported members are assumed, so the maximum factored moment at mid-span is computed as

$$M_{u} = \frac{(1.2w_{D} + 1.6w_{L})l^{2}}{8}$$

where: $w_{D}$ is the specified dead load per unit length; $w_{L}$ is the specified live load per unit length; and, $l$ is the span length of a member.

### 3.4.2 Reliability Analyses

As mentioned previously, the limit state function is $Z = R/Q$. For flexural members, the flexural resistance, $R_{M}$, is

$$R_{M} = PA_{f} \left( d - \frac{A_{f} f_{y}}{1.7 f'_{c} b} \right)$$

where $P$ is the professional factor. The load effect for flexural members, $Q_{M}$, is

$$Q_{M} = \frac{(w_{D}T_{D} + w_{L}T_{L})l^{2}}{8}$$
where: $T_D$ is the factor that accounts for the transformation from the dead load to the dead load effect; and, $T_L$ is the factor that accounts for the transformation from the live load to the live load effect.

The statistical parameters used for reliability analyses for moment summarized from Section 3.3 are shown in Table 3.6. The slab widths (1 m unit length) and member span lengths are assumed deterministic. The statistical parameters for area and line loads are assumed identical. $T_D$ and $T_L$ are already included in the selected parameters for $w_D$ and $w_L$ reported by Ellingwood et al. (1980) and Israel et al. (1987), so bias coefficients of 1.0 and coefficients of variation of 0 are assumed.

The reliability analysis process is as follows:

1. Calculate the design flexural strength $\phi M_n$ using Equations [2.1] and [2.2] or $M_r$ using Equations [2.3] and [2.4].

2. Calculate $w_D$ and $w_L$ by equating the design flexural strength, $\phi M_n$ or $M_r$, to the factored moment, $M_u$, with the given load ratio, $w_L/w_D$, based on Equation [3.11], obtaining

$$ w_D = \frac{8\phi M_n \{\text{or } M_r\}}{[1.2+1.6(w_L/w_D)]l^2} \tag{3.14} $$

and

$$ w_L = \frac{8(w_L/w_D)\phi M_n \{\text{or } M_r\}}{[1.2+1.6(w_L/w_D)]l^2} \tag{3.15} $$

3. Calculate the means and coefficients of variation of the resistances and the load effects using Equations [3.7], [3.8], [3.12] and [3.13].

4. Calculate the reliability index, $\beta_{M_u}$ or $\beta_{M_r}$, using Equation [3.4]. Here, $\beta_{M_u}$ is the reliability index for moment obtained using the strength reduction factors in ACI 318-
14 and $\beta_{Mr}$ is the reliability index for moment obtained using the partial material strength reduction factors.

5. Summarize the results.

The variations of reliability indices for moment, $\beta_M$, with respect to longitudinal reinforcement ratios, $\rho$, for $w_I/w_D$ of 0.5 are shown in Figure 3.1 for $f_c'$ of 25 MPa. Very similar results for $f_c'$ of 45 MPa are shown in Figure B.1 of Appendix B. Clearly, an abrupt discontinuity occurs between the reinforcement ratios of 0.010 and 0.011, which represent the upper and lower limits, respectively, of the ranges for one-way slabs and beams. A smaller discontinuity occurs between $\rho$ of 0.005 and 0.006, which represent the upper and lower limits, respectively, of the ranges for two-way slabs and one-way slabs. In reality, the reliability index variation should not show such discontinuities. The discontinuities are due to the different statistical parameters adopted for the geometric properties of two-way slabs, one-way slabs and beams.

To find reasons for these discontinuities, the design conditions and statistical parameters used for the three representative cross sections in Tables 3.5 and 3.6 were critically reviewed. The nominal values of $b$, $h$, $d$, and $l$ differ, and the reliability index is sensitive to the statistical parameters for $b$ and, particularly, $d$. In reality, any variation of parameters should be gradual instead of abrupt. The analyses were therefore repeated using values of coefficient of variation for $d$, $V_d$, that vary linearly with the reinforcement ratios, as shown in Figure 3.2. The bias coefficients equal 1 for all ranges, so don’t need to be modified. The coefficients of variation for $d$ are the standard deviations shown in Table 3.6 divided by the mean values, and are roughly 0.031, 0.028 and 0.015 for the three ranges of reinforcement ratio. The linear transition was therefore assumed to start at $\rho$ of 0.004, an intermediate value for two-way slabs, and to end at $\rho$ of 0.016, which corresponds approximately to the tension-controlled limit of the section with $f_c'$ of 25 MPa. This variation of the coefficients of variation is reasonable because, as $d$ increases, the coefficient of variation decreases if the standard deviation of $d$ remains constant.
The recalculated results are shown in Figures 3.3 and 3.4 for $f'_{c}$ of 25 MPa and $w_{L}/w_{D}$ of 0.5 and 1.5, respectively. The discontinuities in Figure 3.1 are corrected and the trend lines are continuous. Similar relationships for $f'_{c}$ of 45 MPa are shown in Figures B.2 and B.3 of Appendix B. Moreover, $\beta_{M}$ increases for increased $\rho$, and this is desirable because increasing $\rho$ causes a flexural failure to be less ductile.

The abrupt increase of slope for reliability indices corresponding to ACI 318-14 strength reduction factors in Figure 3.3 for $\rho$ greater than 0.016 is caused by the reduction of $\phi$ for sections that are not tension-controlled. The reason is identical to that abrupt decrease occurring in Figure 2.1 of Chapter 2. The four families of trend lines shown correspond to the four $\phi_{s}$ values, while the differences within each family are due to the four $\phi_{c}$ values. Therefore, the reliability index for moment obtained using the partial material strength reduction factors, $\beta_{Mr}$, is more sensitive to $\phi_{s}$ than to $\phi_{c}$. The slopes shown for lower $\phi_{c}$ values are steeper than those for higher values, but the differences are small. Comparing Figures 3.3 and 3.4, the influence of $w_{L}/w_{D}$ is not large, affecting only the dispersion of the trend lines, and the lines with the higher load ratio are more concentrated. As shown in Figures B.2 and B.3, the influence of increasing $f'_{c}$ to 45 MPa is small, affecting the dispersion in each family: the reliability indices are more concentrated for a typical $\phi_{c}$. In other words, the reliability indices for a typical $\phi_{c}$ are less sensitive to $\phi_{s}$ for $f'_{c}$ of 45 MPa.

According to ASCE 7-10 (ASCE 2010), for a 50-year service period, normal buildings with Risk Category II should exhibit a reliability index of: “3.0 if the failure is not sudden and does not lead to widespread progression of damage; 3.5 if the failure is either sudden or leads to widespread progression of damage; and, 4.0 if the failure is sudden and results in widespread progression of damage”. Therefore, the desired reliability index ranges are 3.0 for slabs and 3.0 to 3.5 for beams. The reliability indices, $\beta_{Mu}$, calculated corresponding to the strength reduction factors from ACI 318-14 for $f'_{c}$ of 25 MPa and $w_{L}/w_{D}$ of 0.5, range from 3.15 for two-way slabs to 3.86 for beams as shown in Figure 3.3. Similarly, the range is 3.05–3.60 for $w_{L}/w_{D}$ of 1.5 as shown in Figure 3.4. For $f'_{c}$ of 45 MPa, the ranges are 3.14–3.28 and 3.04–3.14 as shown in Figures B.2 and B.3 for
$w_L/w_D$ of 0.5 and 1.5, respectively. The lower strength reduction factors, $\phi$, less than 0.90, apply for beams with $f_c'$ of 25 MPa with reinforcement ratios higher than 0.016. $\beta_{Mu}$ is too conservative for these sections. Hence, partial material strength reduction factor combinations should be selected to correspond to reliability indices that satisfy ASCE 7-10 instead of simply duplicating the reliability levels achieved using ACI 318-14.

### 3.4.3 Recommended Partial Material Strength Reduction Factors

Based on Figures 3.3, 3.4, B.2, and B.3, the best partial material strength reduction factor combinations have $\phi_e$ of 0.90. The influence of $\phi_c$ is not as large. The means and standard deviations of the reliability indices for moment, $\beta_{Mr}$, for the three ranges of longitudinal reinforcement ratio are summarized in Tables 3.7–3.9 for $f_c'$ of 25 MPa and in Tables B.7–B.9 of Appendix B for $f_c'$ of 45 MPa. The mean reliability index decreases as $\phi_e$ or $\phi_c$ increases, and the standard deviation of reliability index increases as $\phi_e$ increases and decreases as $\phi_c$ increases. For $\phi_e$ of 0.90 and $\phi_c$ of 0.75, the mean reliability indices computed based on the two load ratios and the two $f_c'$ values are approximately 3.14, 3.22, and 3.36 for $\rho$ of 0.003 to 0.005, 0.006 to 0.010, and 0.011 to 0.018, respectively. Thus this combination yields an appropriate range of reliability indices. Again, as noted previously in Chapter 2, the adoption of $\phi_e$ of 0.90 is desirable, and if a lower $\phi_e$ is chosen, the reliability index will increase and tend to be conservative, but the standard deviation will also increase.

### 3.5 One-way Shear

This section compares reliability indices for one-way shear corresponding to the partial material strength reduction factors with those corresponding to the existing ACI 318-14 criteria. The first-order, second-moment (FOSM) analysis procedure is again adopted.

#### 3.5.1 Assumptions and Design Criteria

Similar to moment, the reliability analysis of shear is based on the FOSM method (Ellingwood et al. 1980). Nominal values of geometric properties, material strengths and live-to-dead load ratios are selected that simulate practical values and are consistent with
the requirements in ACI 318-14, as shown in Table 3.10. The design of the beams is based on Equations [2.13] to [2.19], shear reinforcement limits, minimum thickness limits, specified concrete cover requirements and material strength requirements specified in ACI 318-14. The stirrup yield strength, $f_{ys}$, is 420 MPa and the transverse reinforcement ratio, $\rho_t$, ranges from 0.001 to 0.007 for $f_c'$ of 25 MPa and from 0.001 to 0.010 for $f_c'$ of 45 MPa to represent the ranges permitted by ACI 318-14. However, maximum stirrup spacing criteria are not always satisfied for some of the transverse reinforcement ratios, because the stirrup size is assumed to be a No.3 (9.5 mm diameter) bar and the change of transverse reinforcement ratios is controlled by the spacing.

The typical specified live-to-dead load ratio is identical to that assumed for moment, ranging from 0.5 to 1.5. The specified dead and live loads are determined to exactly achieve the design shear strength, $\phi V_n$ or $V_r$. Tributary-area-based live load reduction factors are again neglected. Simply supported members are assumed, so the maximum factored shear force can be computed as

$$V_u = \frac{(1.2w_D + 1.6w_L)}{2}$$

[3.16]

### 3.5.2 Reliability Analyses

For members resisting shear force, the resistance, $R_V$, is

$$R_V = P \left(0.17 \lambda \sqrt{f_c'b_w}d + \frac{A_vf_{ys}d}{s}\right)$$

[3.17]

where: $\lambda$ is the modification factor to account for the reduced shear strength of lightweight concrete, and equals 1.0 for normalweight concrete; $b_w$ is the web width; $s$ is the center-to-center spacing of the transverse reinforcement; and, $A_v$ is the area within spacing $s$ of the transverse reinforcement.

The load effect for members resisting shear force, $Q_V$, is
\[ Q_v = \frac{(w_D T_D + w_L T_L)l}{2} \]  

[3.18]

The statistical parameters for reliability analyses obtained from the literature are shown in Table 3.11. The stirrup spacing, \( s \), length of the beam, \( l \), and modification factor, \( \lambda \), are assumed deterministic. The professional factor has statistical parameters recommended by Somo and Hong (2006), with a relatively high bias coefficient, 1.47, and a relatively high coefficient of variation, 0.36. The statistical parameters for area and line loads are assumed identical. Similar to moment, \( T_D \) and \( T_L \) are already included in the selected parameters for \( w_D \) and \( w_L \) reported by Ellingwood et al. (1980) and Israel et al. (1987), so bias coefficients of 1.0 and coefficients of variation of 0 are assumed.

The reliability analysis process is as follows:

1. Calculate the design shear strength \( \phi V_n \) using Equations [2.13], [2.14] and [2.15] or \( V_r \) using Equations [2.16], [2.17] and [2.18].

2. Calculate \( w_D \) and \( w_L \) by equating the design shear strength, \( \phi V_n \) or \( V_r \), to the factored shear force, \( V_u \), with the given load ratio, \( w_L/w_D \), based on Equation [3.16], obtaining

\[ w_D = \frac{2\phi V_n \{ \text{or } V_r \}}{\left[ 1.2 + 1.6 \left( \frac{w_L}{w_D} \right) \right] l} \]  

[3.19]

and

\[ w_L = \frac{2 \left( \frac{w_L}{w_D} \right) \phi V_n \{ \text{or } V_r \}}{\left[ 1.2 + 1.6 \left( \frac{w_L}{w_D} \right) \right] l} \]  

[3.20]

3. Calculate the means and coefficients of variation of the resistances and the load effects using Equations [3.7], [3.8], [3.17] and [3.18].

4. Calculate the reliability index, \( \beta_{Vu} \) or \( \beta_{Vr} \), using Equation [3.4], where \( \beta_{Vu} \) is the reliability index for shear obtained using the strength reduction factors in ACI 318-14.
and $\beta_{Vr}$ is the reliability index for shear obtained using the partial material strength reduction factors.

5. Summarize the results.

The reliability indices for shear, $\beta_{V}$, were calculated with respect to transverse reinforcement ratios, $\rho_t$, as shown in Figures 3.5 and 3.6 for $f'_c$ of 25 MPa and $w_L/w_D$ of 0.5 and 1.5, respectively. Similar results were obtained for $f'_c$ of 45 MPa as shown in Figures B.4 and B.5 of Appendix B. The reliability index for shear corresponding to ACI 318-14, $\beta_{Vu}$, increases as $\rho_t$ increases. As the transverse reinforcement ratio increases, however, the failure of the reinforced member becomes more ductile, so this trend may not be particularly desirable. In contrast, the variation of $\beta_{Vr}$ can decrease with the increased $\rho_t$, depending on the various $\phi_s$ and $\phi_e$ values. Again, the four $\phi_s$ values create distinct families of $\beta_{Vr}$ values that are not as diverse as those for moment, and are shown in separate figures. Differences within each family are due to the different $\phi_e$ values. Comparing Figures 3.5 and B.4, the influence of $f'_c$ is slight. Comparing Figures 3.5 and 3.6, the higher $w_L/w_D$ value yields slightly higher reliability indices.

According to ASCE 7-10, for a 50-year service period, normal buildings with Risk Category II should exhibit a reliability range of 3.0 to 3.5 for beams, which is achieved by the best strength reduction factor combination for moment. However, the reliability indices shown in Figures 3.5, 3.6, B.4 and B.5 for shear, range from 2.65 to 2.82, and 2.20 to 3.11 computed for the ACI 318-14 criteria and the various partial material strength reduction factor combinations, respectively. In other words, the safety level for moment is markedly greater than that for shear. This is undesirable, because a shear failure is less ductile than a flexural failure and so has a greater target reliability index.

The reliability indices for shear are sensitive to the statistical parameters assumed for the professional factor. For example, if a bias coefficient of 1.075 and a coefficient of variation of 0.10 are assumed for the professional factor, as recommended by Nowak and Szerszen (2003), the reliability index corresponding to the ACI 318-14 criteria ranges from 4.27 to 4.39 for $f'_c$ of 25 MPa and $w_L/w_D$ of 0.5 as shown in Figure 3.7. The
reliability indices corresponding to the various partial material strength reduction factor combinations range from 3.21 to 4.99. It is therefore necessary to review the basis for the various statistical parameters for the professional factor reported in the literature.

Nowak and Szerszen (2003) recommended statistical parameters for professional factor by modifying slightly the values recommended in Ellingwood et al. (1980) based on their “engineering judgement”. The database used by Ellingwood et al. (1980) contains 62 test beams with stirrups and 96 beams with no stirrups. The database analyzed by Somo and Hong (2006) contains 419 test beams with stirrups and 727 beams with no stirrups, and the total 1146 test beams, includes 878 beams with \( h \geq 300 \text{ mm} \) and \( f'_{c} \geq 20 \text{ MPa} \). Collins (2001) computed professional factors using two databases, one with 413 test results and the other with 776 test results. He observed that the larger database contains much higher number of beams with \( h \leq 350 \text{ mm} \), prestressed beams, and beams without stirrups, and so it is less representative of realistic concrete construction than the smaller database. The three sets of statistical parameters for the professional factor are shown in Table 3.12. The parameters reported by Somo and Hong (2006) are most comprehensively presented, e.g., the parameters are classified by \( a/d \) and the presence of stirrups and consider prestressed members separately. The parameters recommended by Nowak and Szerszen (2003) have the lowest bias coefficient which is conservative but also the lowest coefficient of variation which is unconservative. Somo and Hong (2006) analyzed the largest number of beams, including the database assembled by Bentz (2000) which is the source of 413 test beams for the study of Collins (2001). Therefore, the parameters for professional factor reported by Somo and Hong (2006) are likely the most appropriate.

### 3.5.3 Recommended Partial Material Strength Reduction Factors

Although the reliability indices calculated by applying parameters from Somo and Hong (2006) are lower than the desirable values, the influence of the statistical parameters for the professional factor is consistent for both ACI 318-14 and the partial material strength reduction factors. In other words, the reliability indices increase or decrease consistently in both cases when different professional factor parameters are chosen. Therefore, the reliability indices calculated for ACI 318-14 are assumed adequate and the best partial
material strength reduction factor combinations are selected as those yielding a mean reliability index ratio, $\beta_{Vu}/\beta_{Vr}$, of 1 with the least standard deviation. The means and standard deviations for $\beta_{Vu}/\beta_{Vr}$ are summarized in Table 3.13 for $f_c'$ of 25 MPa and similar results are shown in Table B.10 for $f_c'$ of 45 MPa. The mean increases as $\phi_s$ or $\phi_c$ increases. The standard deviation increases as $\phi_s$ increases and decreases as $\phi_c$ increases. The best partial material strength reduction factor combination is $\phi_s$ of 0.80 and $\phi_c$ of 0.65. Moreover, combinations with $\phi_s$ of 0.80 and $\phi_c$ of 0.70, and $\phi_s$ of 0.85 and $\phi_c$ of 0.60 are close to optimal. These results are identical to those reported for shear in Chapter 2.

### 3.6 Summary and Conclusions

This chapter has presented statistical parameters collection and reliability analyses for members subject to moment and one-way shear using the FOSM method.

For members subjected to moment, the best partial material strength reduction factor combination is $\phi_s$ of 0.90 and $\phi_c$ of 0.75. Similar to Chapter 2, the family with $\phi_s$ of 0.90 is most desirable. If a lower $\phi_c$ value is chosen, the reliability index will increase, and tend to exceed the target values, but the standard deviation will also increase.

For members subjected to one-way shear, the statistical parameters for the professional factor markedly influence the reliability indices. Based on the parameters reported by Somo and Hong (2006), reliability indices corresponding to ACI 318-14 and the partial material strength reduction factors both yield low values, whereas much higher values occur when parameters reported by Nowak and Szerszen (2003) are used. Therefore, because the professional factor has the similar impacts on the reliability indices for ACI 318-14 and the partial material strength reduction factors criteria, and assuming the reliability indices calculated for ACI 318-14 are adequate, partial material strength reduction factors are selected that yield reliability indices that approximate those derived using the ACI 318-14 provisions. The best partial material strength reduction factor combination is $\phi_s$ of 0.80 and $\phi_c$ of 0.65. Moreover, combinations with $\phi_s$ of 0.80 and $\phi_c$ of 0.70, and $\phi_s$ of 0.85 and $\phi_c$ of 0.60 are close to optimal, which are identical to those recommended in Chapter 2.

Chapter 4

4 Derivation of Partial Material Strength Reduction Factors for Combined Moment and Axial Force Based on Reliability Indices

4.1 Introduction

In Chapter 3, the reliability indices presented for moment and one-way shear are based on the first-order, second-moment (FOSM) method. The equations to generate interaction diagrams for combined moment and axial force presented in Chapter 2 are more complicated, however, so a different analysis method, Monte Carlo simulation, is necessary. This chapter presents the reliability analyses for combined moment and axial force to obtain reliability indices based on ACI 318-14 (ACI Committee 318 2014) and the proposed partial material strength reduction factors. The eight geometric and material property combinations of the five column cross sections considered are identical to those presented in Chapter 2.

The objective of this chapter is to select appropriate partial material strength reduction factor combinations that approximately duplicate reliability indices obtained using the current provisions, but may be more uniform for a range of $\gamma$, $f'_{c}$, $\rho_{g}$ and $e/h$ values, which are the ratio of the distance between the outer layers of reinforcement in a column to the overall column depth, the specified compressive strength of concrete, the total reinforcement ratio, and the eccentricity-to-column depth ratio, respectively.

4.2 Methodology

The simulation is conducted using Monte Carlo techniques (e.g., Hong 2015) which are powerful reliability analysis tools. The basic procedure is to generate $n$ sets of random variables and then run the analysis $n$ times to simulate the performance (Hong 2015). The transformations from standard uniform random variables or standard normal random variables to normal, lognormal and Gumbel distributed random variables are derived from Hong (2015).
The simulation is run $10^6$ times for each case using Matlab (Version R2016b; The Mathworks, Inc. 2016) to compute the reliability indices. By simulating $10^6$ times, the reliability indices are not sensitive to a single simulation, so the results tend to be constant.

The means, standard deviations, minimum and maximum values of the reliability indices for ACI 318-14 and each partial material strength reduction factor combination are quantified. The sensitivities of the reliability indices to the partial material strength reduction factor combinations for various geometric and material properties are investigated, and the best partial material strength reduction factor combinations are proposed.

4.3 Assumptions and Design Criteria

Nominal values of geometric and material properties investigated in this chapter are those presented previously in Table 2.10. Again, $\gamma$ of 0.6 and 0.9, $\rho_g$ of 0.01 and 0.04, $f_c'$ of 25 and 45 MPa, and the specified yield strength of reinforcement, $f_y$, of 420 MPa are considered. The live-to-dead load ratios, $L/D$, are assumed to be identical to those adopted previously for moment and shear, of 0.5 and 1.5. The specified dead and live loads are determined to exactly achieve the design strengths. Live load reduction factors due to tributary area are neglected. If they are considered, the range of typical $L/D$ ratios reduces slightly, but the reliability indices computed for a specific $L/D$ value are correct.

The applied axial load and moment are assumed perfectly correlated.

4.4 Reliability Analyses

The limit state function is $Z = g(X) = R/Q$, where $R$ is the resistance and $Q$ is the load effect. For short columns, the limit state function at a given eccentricity, $e_i = M_i/P_i$, is (Israel et al. 1987)

$$g(X) = \sqrt{P_i^2 + \left(\frac{P_i e_i}{h}\right)^2} \left[\left(D_i T_{Di} + L_i T_{Li}\right)^2 + \left(\frac{(D_i T_{Di} + L_i T_{Li}) e_i}{h}\right)^2\right]$$  \[4.1\]
where \( e_i, \ P_i, \ M_i, \ D_i, \ L_i, \ T_{Di}, \) and \( T_{Li} \) are the simulated values of the eccentricity, axial strength, flexural strength, dead load, live load, transformation from the dead load to the dead load effect, and transformation from the live load to the live load effect, respectively. The professional factor is included in \( P_i \) and \( M_i \). In Equation [4.1], \( h \) is the nominal column depth (Hong and Zhou 1999). The eccentricity of the applied load effect, \( e_i \), is equal to the nominal value, \( e \), because the axial load and moment are assumed to be perfectly correlated, with identical bias coefficients and coefficients of variation. The \( e/h \) values investigated are identical to those in Chapter 2, that is, 0 (compression only), 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0, 9.0, 10.0, \(-10.0, \) \(-5.0, \) \(-1.0, \) \(-0.5, \) and 0 (tension only).

The statistical parameters used in the current reliability analysis were obtained from the literature and are shown in Table 4.1. The statistical parameters for column width, \( b \), depth, \( h \), and effective depth, \( d \), depend on measurement errors in the construction process and the parameters for \( d \) are controlled by specified tolerances in ACI 318-14. The standard deviation of \( d \) is assumed to be 1/2 of the tolerance specified in Table 26.6.2.1a in ACI 318-14: this is consistent with the common approximation that the total tolerance range equals four standard deviations. The modulus of elasticity of reinforcement, \( E_{ri} \), is assumed deterministic. The statistical parameters for area loads, point loads, and moments are assumed identical. The transformation from the dead load to the dead load effect, \( T_{Di} \), and the transformation from the live load to the live load effect, \( T_{Li} \), are already included in the selected parameters for \( D \) and \( L \) reported by Ellingwood et al. (1980) and Israel et al. (1987), so bias coefficients of 1.0 and coefficients of variation of 0 are assumed.

The reliability analysis process is as follows:

1. Calculate the design axial strength, \( \phi P_n \) or \( P_r \), and the associated design flexural strength, \( \phi M_n \) or \( M_r \), for a range of \( Z \) values, using Equations [2.21] to [2.45] to generate interaction diagrams. Here, \( Z \) is the ratio of the strain in the extreme tension layer of reinforcement to the yield strain. Interpolate for the specific \( e/h \) values to
obtain corresponding design axial strength, $\phi P_n$ or $P_r$. (This step was done in Chapter 2.)

2. Calculate nominal loads, $D$ and $L$, by equating the design axial strength, $\phi P_n$ or $P_r$, to the factored axial force from ACI 318-14, $P_u = 1.2D + 1.6L$, for the given load ratio, $L/D$. The associated equations are:

$$D = \frac{\phi P_n \{\text{or } P_r\}}{[1.2 + 1.6(L/D)]} \quad \text{[4.2]}$$

and

$$L = \frac{(L/D)\phi P_n \{\text{or } P_r\}}{[1.2 + 1.6(L/D)]} \quad \text{[4.3]}$$

3. Calculate the resistance: generate $10^6$ sets of random variables using the statistical parameters shown in Table 4.1, and run the simulation to derive $10^6$ distinct interaction diagrams by using Equations [2.21] to [2.45] with strength reduction factors equal to 1 and accounting for the professional factor.

4. Calculate the load effects: generate $10^6$ sets of random variables for load effects at each specified eccentricity using the statistical parameters shown in Table 4.1.

5. Interpolate on each of the $10^6$ interaction diagrams to determine the value of the limit state function, Equation [4.1], at each specified eccentricity.

6. Calculate the number of failures and compute the associated reliability index for combined moment and axial force, $\beta_{PMu}$ or $\beta_{PMr}$, using $\beta = -\Phi^{-1}(P_f)$ (Hong 2015). Here, $\beta_{PMu}$ is the reliability index for combined moment and axial force obtained using the strength reduction factors in ACI 318-14, $\beta_{PMr}$ is the reliability index for combined moment and axial force obtained using the partial material strength reduction factors, $\Phi(\bullet)$ is the cumulative distribution function of the standard normal distribution, and $P_f$ is the probability of failure.
7. Summarize the results.

The Matlab (Version R2016b; The Mathworks, Inc. 2016) codes used to conduct the process for Column Section 1 (square section with three bars in each face) and Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), two representative cross sections, are presented in Appendix C.

To save time and avoid unnecessary calculations, only four pairs of partial material strength reduction factors are analyzed for tied columns, combinations with $\phi_s$ of 0.85 and 0.90, and $\phi_c$ of 0.60 and 0.65.

For Column Section 1 (square section with three bars in each face), the reliability indices for combined moment and axial force corresponding to ACI 318-14, $\beta_{PMu}$, with respect to $el/h$ are shown in Figures 4.1a and 4.1b for the eight property combinations with $L/D$ of 0.5 for $el/h > 0$ and $el/h < 0$, respectively. The vertical dotted lines show the range of $el/h$ at the balance point. For $el/h$ approximately ranging from 0.1 to 0.38, all of the eight property combinations do not reach the minimum value of $e_{ubal}/h$, where $e$ corresponds to the balanced failure for ACI 318-14, so they are compression-controlled. In this region, similar to the trend of design combined flexural and axial strength ratio, $\alpha_{PM}$, described in Chapter 2, the most influential property is $\rho_g$. For $\rho_g$ of 4%, $\beta_{PMu}$ reaches 4.06, and for $\rho_g$ of 1%, $\beta_{PMu}$ reaches 2.44, causing inconsistent reliability indices with varying $el/h$. Varying $f_c'$ causes small changes for lower $\rho_g$, but large changes for higher $\rho_g$. And again, the least influential parameter is $\gamma$. For $el/h$ approximately ranging from 0.38 to 0.88, some of the cases shown reach the balance point, but others do not. For $el/h$ approximately ranging from 0.88 to 10, all of the eight property combinations equal or exceed the maximum value of $e_{ubal}/h$, so they are in the transition or tension-controlled regions. The two lines corresponding to Property Combination 2 ($\gamma$ of 0.6, $f_c'$ of 25 MPa, and $\rho_g$ of 0.04) and Property Combination 4 ($\gamma$ of 0.6, $f_c'$ of 45 MPa, and $\rho_g$ of 0.04), differ from the others shown because they remain in the transition region until $el/h$ equals 10. For $el/h$ less than 0 shown in Figure 4.1b, the sections are subjected to tension. In the tension-controlled region, the influences of $\gamma$, $f_c'$ and $\rho_g$ on $\beta_{PMu}$ become small. Results for $L/D$ of 1.5 are shown in Figure C.1 of Appendix C. The influence of $L/D$ is small.
For the partial material strength reduction factors $\phi_s$ of 0.90 and $\phi_c$ of 0.60, $\beta_{PMr}$ values for Column Section 1 are shown in Figures 4.2a and 4.2b for the eight property combinations with $L/D$ of 0.5 for $e/h > 0$ and $e/h < 0$, respectively. These $\beta_{PMr}$ values are relatively uniform, ranging from 2.75 to 3.40 compared to the range of 2.44 to 4.06 for the current ACI 318-14 criteria shown in Figures 4.1a and 4.1b. This indicates an advantage of using partial material strength reduction factors. In the compression-controlled region, the influence of $\gamma$ is very small and influences of $f_{c'}$ and $\rho$ are smaller than those shown in Figure 4.1a. In the tension-controlled region, $\gamma$ has a more significant impact on $\beta_{PMr}$ for increased $e/h$ values. Results for $L/D$ of 1.5 are shown in Figure C.2 of Appendix C. The influence of $L/D$ is small.

According to ASCE 7-10 (ASCE 2010), for a 50-year service period, normal buildings with Risk Category II should exhibit a reliability index range of 3.0 to 4.0 for columns. Figures 4.3a and 4.3b show the reliability indices for combined moment and axial force, $\beta_{PM}$, for Column Section 1, Property Combination 1 ($\gamma$ of 0.6, $f_{c'}$ of 25 MPa, and $\rho_s$ of 0.01) and $L/D$ of 0.5 for $e/h > 0$ and $e/h < 0$, respectively. The dotted vertical line in Figure 4.3a shows $e_{ubal}/h$ of 0.42, the $e$ corresponding to the balanced failure for ACI 318-14. The two solid vertical lines represent the range of $e$ values corresponding to the balanced failures for the sixteen partial material strength reduction factor combinations (although there are only four combinations shown in the figure), from $(e_{ubal}/h)_{min}$ of 0.43 to $(e_{ubal}/h)_{max}$ of 0.50. When $e/h > 0$, the reliability index corresponding to ACI 318-14 decreases abruptly for eccentricities greater than that corresponding to the balance point, because the strength reduction factor in ACI 318-14, $\phi$, increases from 0.65 to 0.90 for tied columns. In the compression-controlled region, two families of lines are defined by the two $\phi_c$ values, and the differences within each family are due to the two $\phi_s$ values. As the eccentricity increases, the influence of steel strength becomes more significant than that of the concrete strength, so the two families are defined by the two $\phi_s$ values. When $e/h < 0$, $\beta_{PM}$ increases slightly as the absolute value of $e/h$ increases. In this case, the influence of $\phi_s$ on $\beta_{PMr}$ is greater because the tensile strength of concrete is negligible and does not contribute to the strength.
Results for the other seven property combinations and $L/D$ of 0.5 are shown in Figures C.3–C.9 of Appendix C. In the compression-controlled region where the impact of $\phi_c$ is greatest, $\beta_{PMr}$ corresponding to the partial material strength reduction factor combinations with $\phi_c$ of 0.60 approaches $\beta_{PMu}$ when $\rho_g$ equals 0.01. When $\beta_{PMu}$ is too conservative, i.e. for $\rho_g$ of 0.04, $\beta_{PMr}$ values for $\phi_c$ of 0.60 still fall in an appropriate range. In the tension-controlled region where $\phi_t$ is more influential, $\beta_{PMr}$ corresponding to the combinations with $\phi_c$ of 0.90 approaches $\beta_{PMu}$.

Values of $\beta_{PM}$ for Column Sections 2, 3 and 4 and $L/D$ of 0.5 are shown in Figures C.10–C.33 of Appendix C. The reliability indices, impacts of $\phi_t$ and $\phi_c$, and the best partial material strength reduction factors are similar to those shown for Column Section 1.

For Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), the $\phi$ values range from 0.75 to 0.90. The four partial material strength reduction factor combinations analyzed for the tied columns are therefore not appropriate. The analysis results for Column Section 5 presented in Chapter 2 indicate that: when the failure is compression-controlled, the partial material strength reduction factor combinations with $\phi_c$ of 0.70 are the best; and, when the failure is tension-controlled, the combinations with $\phi_c$ of 0.90 and 0.95 are the best. Therefore, two combinations with $\phi_t$ of 0.90 and $\phi_c$ of 0.70, and $\phi_t$ of 0.95 and $\phi_c$ of 0.70 are investigated.

Figures 4.4a and 4.4b show $\beta_{PM}$ for Column Section 5, Property Combination 1 ($\gamma$ of 0.6, $f'_c$ of 25 MPa, and $\rho_g$ of 0.01) and $L/D$ of 0.5 for $e/h > 0$ and $e/h < 0$, respectively. The reliability index corresponding to ACI 318-14 decreases less abruptly as the eccentricity increases beyond that at the balance point compared with that shown in Figure 4.3a. In this case, the difference between the two $\phi$ values is $(0.90 - 0.75) = 0.15$, which is markedly smaller than $(0.90 - 0.65) = 0.25$ for the tied column. For the other seven property combinations and $L/D$ of 0.5, the ranges of reliability index are shown in Figures C.34–C.40 of Appendix C. The influences of geometric and material properties, load ratios, and partial material strength reduction factors are similar to those for Column
Section 1. Inspection of these figures indicates that the reliability indices corresponding to the combination with \( \phi_s \) of 0.90 and \( \phi_c \) of 0.70 are less variable and slightly conservative compared to those corresponding to the ACI 318-14 criteria.

### 4.5 Recommended Partial Material Strength Reduction Factors

For Column Section 1 (square section with three bars in each face), based on Figures 4.3, and C.3–C.9, the best partial material strength reduction factor combination is \( \phi_s \) of 0.90 and \( \phi_c \) of 0.60. Table 4.2 shows the means, standard deviations, minima and maxima of the reliability indices based on the eight property combinations and the two \( L/D \) ratios. The category of the four ranges of \( e/\h \) is same with that presented in Chapter 2. The combination with \( \phi_s \) of 0.90 and \( \phi_c \) of 0.60 is the best: for any range of \( e/\h \), the minimum reliability indices are not smaller than those obtained using ACI 318-14; the means and maxima are not excessively conservative; and, the standard deviations are relatively small. Adopting this combination of partial material strength reduction factors yields reliability indices that are bounded by those obtained using the ACI 318-14 criteria. The proposed partial material strength reduction factors yield reliability indices that are neither unnecessary large to cause the strength to be excessive nor excessively low to make the column unsafe. Similar results corresponding to Column Sections 2, 3 and 4 are shown in Tables 4.3–4.5, respectively, indicating that the longitudinal reinforcement arrangement is not a significant factor.

For Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), the means, standard deviations, minima and maxima of the reliability indices are shown in Table 4.6. The combination with \( \phi_s \) of 0.90 and \( \phi_c \) of 0.70 is the best.

Alternatively, the maximum axial compressive strengths defined in ACI 318-14 are limited to 0.80 and 0.85 of the axial compressive strengths at zero eccentricity for tied and spirally reinforced columns, respectively, and they are approximate axial strengths at \( e/\h \) of 0.10 and 0.05, respectively (ACI Committee 318 2014). These values can be
reviewed and the excessively high reliability indices for columns with the higher reinforcement ratio may reduce.

4.6 Summary and Conclusions

This chapter has presented the reliability indices obtained using Monte Carlo simulation for five column cross sections and eight geometric and material property combinations for each cross section. Two live-to-dead load ratios are considered.

When the section is compression-controlled, the reliability index corresponding to ACI 318-14 is very sensitive to the reinforcement ratio, $\rho_g$, because the coefficient of variation of $f_y$ is markedly less than that of $f'_{c}$. When the reinforcement ratio increases, the reliability index also increases (Israel et al. 1987). When the section is tension-controlled, the influence of $\gamma$ becomes greater for $\beta_{PMr}$, while less for $\beta_{PMu}$. The influence of $f'_{c}$ on the reliability index is larger in the compression-controlled region than in the tension-controlled region. For the partial material strength reduction factors, $\phi_s$ is more influential in the tension-controlled region, while $\phi_c$ is more influential in the compression-controlled region. The $L/D$ ratio has negligible effects on the computed reliability indices.

For columns with tied reinforcement, the best partial material strength reduction factor combination is $\phi_s$ of 0.90 and $\phi_c$ of 0.60, which is also identical to the values obtained in Chapter 2. The four tied column cross sections investigated yield the similar results, indicating that the longitudinal reinforcement arrangement is not a significant factor.

For columns with spiral reinforcement, the best partial material strength reduction factor combination is $\phi_s$ of 0.90 and $\phi_c$ of 0.70.

Therefore, $\phi_s$ of 0.90 is the best for both tied and spirally reinforced columns. A unique $\phi_c$ value is appropriate for spirally reinforced columns to account for the advantages of confinement that mainly impact the compression-controlled region.

Chapter 5

5 Summary and Conclusions

This chapter presents a summary of the work conducted in this study, lists the conclusions and recommends some suggestions for future work.

5.1 Summary

ACI 318-14 (ACI Committee 318 2014) defines an overall strength reduction factor to account for the probability of understrength. However, it leads to some unsatisfactory results, particularly inconsistencies in the transition region of the interaction diagram, between the compression-controlled and tension controlled regions (e.g., Gamble 1998, 2015), and so non-unique moment capacities for one axial strength level for sections with wide flanges (Lequesne and Pincheira 2014). The statistical parameters that quantify the professional factor for shear since previous calibrations (Israel et al. 1987; Nowak and Szerszen 2003) have also changed markedly (Somo and Hong 2006). Therefore, the present study proposes partial material strength reduction factors for concrete, \( \phi_c \), and reinforcing steel, \( \phi_s \), that yield similar design strengths and more consistent reliability indices compared to those based on the strength reduction factors, \( \phi \), in ACI 318-14. Three structural actions acting on non-prestressed members are investigated: moment; one-way shear; and, combined moment and axial force.

The comparison of design strengths is presented in Chapter 2. For members subjected to moment, singly reinforced sections with concrete compressive strengths, \( f_c' \), of 25 and 45 MPa, reinforcement yield strength, \( f_y \), of 420 MPa, and reinforcement ratio, \( \rho \), ranging from 0.003 to 0.018 are investigated. For members subjected to shear, rectangular beam sections with the same material strengths and ranges of transverse reinforcement ratio, \( \rho_t \), from 0.001 to 0.007 for \( f_c' \) of 25 MPa and 0.001 to 0.010 for \( f_c' \) of 45 MPa are studied. For members subjected to combined moment and axial force, five column cross sections including square section with three bars in each face, square section with three bars in two end faces only, square section with three bars in two side faces only, tied circular
section with eight bars evenly distributed around the perimeter, and spirally reinforced circular section with eight bars evenly distributed around the perimeter are investigated. For each column section, eight geometric and material property combinations are investigated, specifically, the ratios of the distance between the outer layers of reinforcement to the overall column depth, \( \gamma \), of 0.6 and 0.9, \( f'_{c} \) of 25 and 45 MPa, \( f_{y} \) of 420 MPa and total reinforcement ratios, \( \rho_{g} \), of 0.01 and 0.04. The design strengths of each section are calculated using ACI 318-14 and the partial material strength reduction factors. Then design strength ratios, defined as the design strength obtained using ACI 318-14 to that obtained using a particular pair of partial material strength reduction factors, are calculated. The sensitivities of the design strength ratios to the geometric and material properties and the partial material strength reduction factors are analyzed, and the best partial material strength reduction factor combinations are proposed.

The reliability analyses for members resisting moment and shear are presented in Chapter 3. The reliability model and the first-order, second-moment (FOSM) method are described. Statistical parameters for geometric properties, material strengths, professional factors and load effects collected from the literature are summarized and those used for the subsequent reliability analyses are listed. The reliability indices are calculated for the different geometric and material properties, and two live-to-dead load ratios, \( w_{L}/w_{D} \), of 0.5 and 1.5 for varying \( \rho \) and \( \rho_{t} \) for moment and shear, respectively, using Microsoft Excel (Version 2013; Microsoft 2013). The means and standard deviations of the reliability indices for each partial material strength reduction factor combination are quantified. The sensitivities of the reliability indices to the geometric and material properties, partial material strength reduction factors, load ratios, and statistical parameters are analyzed, and the best partial material strength reduction factor combinations are proposed.

The reliability analyses for members resisting combined moment and axial force are presented in Chapter 4. The analyses are conducted using Monte Carlo simulation (Hong 2015) because the equations to generate interaction diagrams are relatively complicated. The sections and various geometric and material properties investigated are identical to those for design strength calculations in Chapter 2. Two live-to-dead load ratios, 0.5 and
1.5 are again investigated. The applied moment and axial force are assumed perfectly correlated and reliability indices are computed for a range of specific eccentricities. To save time and avoid unnecessary calculations, only four pairs of partial material strength reduction factors are analyzed for tied columns, combinations with \( \phi_s \) of 0.85 and 0.90, and \( \phi_c \) of 0.60 and 0.65. For spirally reinforced columns, two pairs of partial material strength reduction factors are analyzed, combinations with \( \phi_s \) of 0.90 and 0.95, and \( \phi_c \) of 0.70. The simulation is run \( 10^6 \) times for each case using Matlab (Version R2016b; The Mathworks, Inc. 2016). The means, standard deviations, minima and maxima for typical reliability indices for each combination are quantified. The sensitivities of the reliability indices to the partial material strength reduction factor combinations are investigated for various geometric and material properties, and the best combinations are proposed.

5.2 Conclusions

The following conclusions pertain to the design strength analysis results:

1. The design flexural strength ratio, \( \alpha_M \), which is defined as the design flexural strength obtained using the strength reduction factor in ACI 318-14 to that obtained using a particular pair of partial material strength reduction factors, is sensitive to \( \phi_s \) and relatively insensitive to \( \phi_c \). In the tension-controlled sections, the combination with \( \phi_s \) of 0.90 and \( \phi_c \) of 0.75 is the best. If the section is in the transition region, the combination with \( \phi_s \) of 0.95 and \( \phi_c \) of 0.65 is the best. And any combination with \( \phi_s \) of 0.90 is satisfactory for moment. The results are insensitive to \( f'_{c} \).

2. The design shear strength ratio, \( \alpha_V \), is also sensitive to \( \phi_s \) and relatively insensitive to \( \phi_c \), but the influences of these two factors are not as distinct as they are for moment. The best partial material strength reduction factor combination is \( \phi_s \) of 0.80 and \( \phi_c \) of 0.65. Combinations with \( \phi_s \) of 0.80 and \( \phi_c \) of 0.70, and \( \phi_s \) of 0.85 and \( \phi_c \) of 0.60 are close to optimal. The influence of \( f'_{c} \) is again slight.

3. For tied columns, in the compression-controlled region, the design combined flexural and axial strength ratio, \( \alpha_{PM} \), is sensitive to \( \phi_c \), and \( \phi_c \) of 0.60 is the best. The
influences of $\gamma, f'_c, \rho_g$ are very small, moderate, and relatively large, respectively. In the tension-controlled region, $\alpha_{PM}$ is sensitive to $\phi_s$ and $\phi_c$ of 0.90 is the best. The influence of $\gamma$ becomes more significant, that of $\rho_g$ is moderate, and that of $f'_c$ is limited. The $\alpha_{PM}$ value varies markedly in the transition region where failure mode changes from compression-induced to tension-initiated, because $\phi$ in ACI 318-14 increases from 0.65 to 0.90.

4. For spirally reinforced circular columns, $\alpha_{PM}$ increases markedly in the compression-controlled region compared to those for tied columns, which is due to the strength reduction factor in ACI 318-14, $\phi$, being 0.75 for spirally reinforced columns instead of 0.65. In the compression-controlled region, $\phi_c$ of 0.70 is the best and in the tension-controlled region, $\phi_s$ of both 0.90 and 0.95 are the best.

The following conclusions pertain to the reliability analysis results:

5. The reliability index for members subjected to moment corresponding to partial material strength reduction factors, $\beta_{Mr}$, is more sensitive to $\phi_s$ than to $\phi_c$. The best partial material strength reduction factor combination is $\phi_s$ of 0.90 and $\phi_c$ of 0.75. As for the design strength comparison, any combination with $\phi_s$ of 0.90 is satisfactory. The influences of $f'_c$ and $wL/wD$ are small.

6. The reliability index for members subjected to one-way shear corresponding to partial material strength reduction factors, $\beta_{Vs}$, is more sensitive to $\phi_s$ than to $\phi_c$, but the differences are not as large as they are for moment. The best partial material strength reduction factor combination is $\phi_s$ of 0.80 and $\phi_c$ of 0.65. Moreover, combinations with $\phi_s$ of 0.80 and $\phi_c$ of 0.70, and $\phi_s$ of 0.85 and $\phi_c$ of 0.60 are close to optimal, which are identical to the results based on the design strengths. Again, the influences of $f'_c$ and $wL/wD$ are small.

7. The reliability indices for one-way shear range from 2.65 to 2.82, and 2.20 to 3.11 computed for the ACI 318-14 criteria and the various partial material strength reduction factor combinations, respectively. These ranges are markedly lower than
those for moment, which is not desirable because shear failures are less ductile than flexural failures. The reliability indices for shear are very sensitive, however, to the statistical parameters assumed for the professional factor. If the statistical parameters assumed previously by Nowak and Szerszen (2003) are adopted, the reliability indices for shear increase markedly. However, the statistical parameters reported by Somo and Hong (2006) are more appropriate because they are based on larger sample sizes, classification of parameters by $a_c/d$ and the presence of stirrups, and considering prestressed members separately. The influence of the statistical parameters for the professional factor selected is consistent for both ACI 318-14 and the partial material strength reduction factors criteria.

8. For tied columns, in the compression-controlled region, the reliability index for members subjected to combined moment and axial force corresponding to partial material strength reduction factors, $\beta_{PMr}$, is sensitive to $\phi_c$, and $\phi_c$ of 0.60 is the best. In the tension-controlled region, $\beta_{PMr}$ is sensitive to $\phi_s$, and $\phi_s$ of 0.90 is the best. For ACI 318-14, $\beta_{PMr}$ varies markedly with $\rho_c$. For the combination with $\phi_s$ of 0.90 and $\phi_c$ of 0.60, however, the $\beta_{PMr}$ values are more consistent. The geometric and material properties and load ratios do not appreciably affect these results. The results are also essentially identical for the four tied column sections investigated, which indicates that the reinforcement arrangement is not a significant factor.

9. For spirally reinforced columns, the influences of material and geometric properties, load ratios, and partial material strength reduction factors are similar to those for tied columns. The best combination is $\phi_s$ of 0.90 and $\phi_c$ of 0.70. Therefore, $\phi_s$ of 0.90 is the best for both tied and spirally reinforced columns, while a unique $\phi_c$ value is appropriate for spirally reinforced columns to account for the advantages of confinement that mainly impact the compression-controlled region.

10. Although no single combination of $\phi_s$ and $\phi_c$ is the best for members resisting moment, shear, or combined moment and axial force, the recommended partial material strength reduction factors are $\phi_s$ of 0.90 and $\phi_c$ of 0.60 for slabs and beams subjected to moment, beams subjected to one-way shear, and tied columns, or $\phi_c$ of
0.70 for spirally reinforced columns. Alternatively, for shear, the combination with $\phi_s$ of 0.80 and $\phi_c$ of 0.65 is recommended.

5.3 Suggestions for Future Work

1. The oldest statistical parameters used in this study trace back to 1979. Control of the construction process and material quality may have since improved. Research to determine more current statistical parameters for the geometric properties, material strengths, professional factors, and load effects should be carried out and the recommended partial material strength reduction factors should be reviewed based on these new parameters.

2. The structural actions investigated in this study are moment, one-way shear, and combined moment and axial force. Other actions or structural elements, such as two-way shear, torsion, bearing, brackets and corbels, should be investigated in the future.

3. The reliability index for one-way shear is very sensitive to the statistical parameters used to quantify the professional factor. The basic equations for one-way shear strength in ACI 318 have not changed for more than five decades (Belarbi et al. 2017). Significant changes have occurred in other codes, and the deficiencies of the current provisions include: (1) ignoring the size effect in the calculation of the shear strength resisted by concrete, $V_c$; (2) ignoring the presence of shear reinforcement in the computation of $V_c$; (3) assuming the angle of diagonal compression is fixed at 45° irrespective of the amount of reinforcement; and other factors (Belarbi et al. 2017). The provisions for one-way shear should be improved and new statistical parameters for the professional factor should be derived, based on these new criteria.

4. The maximum axial compressive strengths defined in ACI 318-14 are limited to 0.80 and 0.85 of the axial compressive strengths at zero eccentricity for tied and spirally reinforced columns, respectively, and they are approximate axial strengths at $e/h$ of 0.10 and 0.05, respectively (ACI Committee 318 2014). These values should be reviewed and reliability analyses should be conducted.

A.1 Codes

The Matlab (Version R2016b; The Mathworks, Inc. 2016) codes used to obtain design combined flexural and axial strength ratios, $\alpha_{PM}$, corresponding to specific $e/h$ values for Column Section 1 (square section with three bars in each face) and Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), two representative cross sections, are as follows:

A.1.1 Notation

% Notation
% $a=$depth of equivalent rectangular stress block (mm)
% $A=$area of compression segment of circular section (mm$^2$)
% $A_{st}=$total area of nonprestressed longitudinal reinforcement (mm$^2$)
% $A_{s1}=$area of the 1st layer of reinforcement (mm$^2$)
% $A_{s2}=$area of the 2nd layer of reinforcement (mm$^2$)
% $A_{s3}=$area of the 3rd layer of reinforcement (mm$^2$)
% $A_{s4}=$area of the 4th layer of reinforcement (mm$^2$)
% $A_{s5}=$area of the 5th layer of reinforcement (mm$^2$)
% $b=$width of column (mm)
% _b=boundary
% _bal=at balance point
% $c=$distance from extreme compression fiber to neutral axis (mm)
% _com=combination
% $C_c=$nominal compressive force in concrete (kN)
% $C_{rc}=$factored compressive force in concrete for partial material strength reduction factors format (kN)
% $d_1=$distance from extreme compression fiber to the 1st layer of reinforcement (mm)
% $d_2=$distance from extreme compression fiber to the 2nd layer of reinforcement (mm)
% $d_3=$distance from extreme compression fiber to the 3rd layer of reinforcement (mm)
% $d_4=$distance from extreme compression fiber to the 4th layer of reinforcement (mm)
% $d_5=$distance from extreme compression fiber to the 5th layer of reinforcement (mm)
% $eoverh=$the specific e/h value
% $eoverh_2=$the specific e/h value, including extreme values
% e_r=design eccentricity for partial material strength reduction factors format (m)
% e_u=design eccentricity for ACI 318-14 (m)
% E_s=modulus of elasticity of reinforcement (MPa)
% f_c=specified compressive strength of concrete (MPa)
% f_s1=stress in the 1st layer of reinforcement (MPa)
% f_s2=stress in the 2nd layer of reinforcement (MPa)
% f_s3=stress in the 3rd layer of reinforcement (MPa)
% f_s4=stress in the 4th layer of reinforcement (MPa)
% f_s5=stress in the 5th layer of reinforcement (MPa)
% f_y=specified yield strength for nonprestressed reinforcement (MPa)
% F_rs1=factored force in the 1st layer of reinforcement for partial material strength reduction factors format (kN)
% F_rs2=factored force in the 2nd layer of reinforcement for partial material strength reduction factors format (kN)
% F_rs3=factored force in the 3rd layer of reinforcement for partial material strength reduction factors format (kN)
% F_rs4=factored force in the 4th layer of reinforcement for partial material strength reduction factors format (kN)
% F_rs5=factored force in the 5th layer of reinforcement for partial material strength reduction factors format (kN)
% F_s1=nominal force in the 1st layer of reinforcement (kN)
% F_s2=nominal force in the 2nd layer of reinforcement (kN)
% F_s3=nominal force in the 3rd layer of reinforcement (kN)
% F_s4=nominal force in the 4th layer of reinforcement (kN)
% F_s5=nominal force in the 5th layer of reinforcement (kN)
% h=overall depth of column (mm)
% hovere=the specific h/e value
% hovere_r=h/e_r, where e_r=design eccentricity for partial material strength reduction factors format (m)
% hovere_u=h/e_u, where e_u=design eccentricity for ACI 318-14 (m)
% hovere_2=the specific h/e value, including extreme values
% M_n=nominal flexural strength (kN.m)
% M_r=design flexural strength for partial material strength reduction factors format (kN.m)
% _pri=prime
% pro=property
% P_n=nominal axial strength (kN)
% P_nt=nominal axial tensile strength (kN)
% P_o=nominal axial strength at zero eccentricity (kN)
% P_r=design axial strength for partial material strength reduction factors format (kN)
% P_rmax= maximum design axial compressive strength for partial material strength reduction factors format (
% (kN)
% P_ro= design axial strength at zero eccentricity for partial material strength reduction factors format
% (kN)
% P_rt= design axial tensile strength for partial material strength reduction factors format (kN)
% _s_= subscript
% _s= sort
% _sam= samples
% Z= ratio of strain in extreme tension layer of reinforcement to yield strain

% alpha_PM= design combined flexural and axial strength ratio, equal to design combined flexural and axial
% strength obtained using strength reduction factors in ACI 318-14 to that obtained using partial
% material strength reduction factors
% beta_1= factor relating depth of equivalent rectangular compressive stress block to depth of neutral axis
% gamma= ratio of distance between outer layers of reinforcement in column to overall column depth
% epsilon_s1= strain in the 1st layer of reinforcement
% epsilon_s2= strain in the 2nd layer of reinforcement
% epsilon_s3= strain in the 3rd layer of reinforcement
% epsilon_s4= strain in the 4th layer of reinforcement
% epsilon_s5= strain in the 5th layer of reinforcement
% epsilon_y= yield strain of reinforcement
% angle_theta= angle theta, angle used to calculate compression segment of circular column
% rho_g= total reinforcement ratio, equal to ratio of total longitudinal reinforcement area to cross-
% sectional area of column
% phi= strength reduction factor in ACI 318-14
% phi_c= partial material strength reduction factor for concrete
% phi_s= partial material strength reduction factor for reinforcing steel
% phi_sc= a pair of partial material strength reduction factors
% phiM_n= design flexural strength in ACI 318-14 (kN.m)
% phiP_n= design axial strength in ACI 318-14 (kN)
% phiP_nmax= maximum design axial compressive strength in ACI 318-14 (kN)
% phiP_nt= design axial tensile strength in ACI 318-14 (kN)
% phiP_o= design axial strength at zero eccentricity in ACI 318-14 (kN)

end \\
end 
end
Appendix B-Supplementary Information for Chapter 3

B.1 Supplementary Information for Concrete Compressive Strength

Table B.2 shows bias coefficients and coefficients of variation of $F_1$, for cast-in-place and precast concrete. The weighted average computed based on the data reported by Nowak and Szerszen (2003) has a bias coefficient of 1.238 and a coefficient of variation of 0.127 for cast-in-place concrete and a bias coefficient of 1.217 and a coefficient of variation 0.131 for precast concrete. Bartlett (2007) assumed $F_1$ for cast-in-place concrete has a bias coefficient of 1.27 and a coefficient of variation of 0.122.

Table B.3 shows the bias coefficients and coefficients of variation of $F_2$ for cast-in-place and precast concrete (Bartlett 2007). Table B.4 shows the bias coefficients and coefficients of variation of $F_{i-p}$ for cast-in-place and precast concrete (Bartlett and MacGregor 1999).

Table B.5 shows statistical parameters for in-situ concrete compressive strength reported by Ellingwood et al. (1980). The values in this table intend to account for $F_1$, $F_2$, $F_{i-p}$ and $F_r$. There is no distinction between cast-in-place or precast concrete reported.

C.1 Codes

The Matlab (Version R2016b; The Mathworks, Inc. 2016) codes used to calculate reliability indices for combined moment and axial force, $\beta_{PM}$, for Column Section 1 (square section with three bars in each face) and Column Section 5 (spirally reinforced circular section with eight bars evenly distributed around the perimeter), two representative cross sections, are as follows:

The calculation needs to refer the results saved in alpha_PM_S1.mat and alpha_PM_S5.mat, which are presented in Appendix A.

C.1.1 Notation

% a=depth of equivalent rectangular stress block (mm)
% A=area of compression segment of circular section (mm^2)
% A_st=total area of nonprestressed longitudinal reinforcement (mm^2)
% A_s1=area of the 1st layer of reinforcement (mm^2)
% A_s2=area of the 2nd layer of reinforcement (mm^2)
% A_s3=area of the 3rd layer of reinforcement (mm^2)
% A_s4=area of the 4th layer of reinforcement (mm^2)
% A_s5=area of the 5th layer of reinforcement (mm^2)
% b=width of column (mm)
% bias_=bias coefficient
% c=distance from extreme compression fiber to neutral axis (mm)
% _com=combination
% _cur=calculation corresponding to ACI 318-14
% _cur1=calculation corresponding to ACI 318-14 and L/D=0.5
% _cur2=calculation corresponding to ACI 318-14 and L/D=1.5
% C_c=compressive force in concrete (kN)
% CoV_=coefficient of variation
% _d_1=distance from extreme compression fiber to the 1st layer of reinforcement (mm)
% _d_2=distance from extreme compression fiber to the 2nd layer of reinforcement (mm)
% _d_3=distance from extreme compression fiber to the 3rd layer of reinforcement (mm)
% _d_4=distance from extreme compression fiber to the 4th layer of reinforcement (mm)
% _d_5=distance from extreme compression fiber to the 5th layer of reinforcement (mm)
% D=dead load
% e=eccentricity (mm)
% eoverh=the specific e/h value
% eoverh_2=the specific e/h value, including extreme values
% E_s=modulus of elasticity of reinforcement (MPa)
% f_c=specified compressive strength of concrete (MPa)
% f_s1=stress in the 1st layer of reinforcement (MPa)
% f_s2=stress in the 2nd layer of reinforcement (MPa)
% f_s3=stress in the 3rd layer of reinforcement (MPa)
% f_s4=stress in the 4th layer of reinforcement (MPa)
% f_s5=stress in the 5th layer of reinforcement (MPa)
% f_y=specified yield strength for nonprestressed reinforcement (MPa)
% F_s1=force in the 1st layer of reinforcement (kN)
% F_s2=force in the 2nd layer of reinforcement (kN)
% F_s3=force in the 3rd layer of reinforcement (kN)
% F_s4=force in the 4th layer of reinforcement (kN)
% F_s5=force in the 5th layer of reinforcement (kN)
% g=limit state function
% h=overall depth of column (mm)
% hovere=h/e
% _i=simulated value
% _f=value to count numbers of failure
% L=live load
% LoverD=ratio of live load to dead load, L/D
% mean_=mean
% M=flexural strength (kN.m)
% n=numbers of simulation in one subset
% _neg=negative
% _n_f=numbers of failure
% N=total numbers of simulation
% _pri=prime
% pro=property
% _pro=calculation corresponding to partial material strength reduction factors
% _pro1=calculation corresponding to partial material strength reduction factors and L/D=0.5
% _pro2=calculation corresponding to partial material strength reduction factors and L/D=1.5
% P=axial strength (kN)
% _P_f=probability of failure
% P_max=maximum axial compressive strength (kN)
% P_o=axial strength at zero eccentricity (kN)
% P_r=design axial strength for partial material strength reduction factors format (kN)
% Prof=professional factor
% P_t=axial tensile strength (kN)
% rn_n=standard normally distributed random number
% rn_u=standard uniformly distributed random number
% s_=subscript
% _s=sort
% _sam=samples
% std_=standard deviation
% T_D=factor to account for transformation from dead load to dead load effect
% T_L=factor to account for transformation from live load to live load effect
% Z=ratio of strain in extreme tension layer of reinforcement to yield strain

% alpha_=dispersion parameter for Gumbel distribution
% beta_PMr1=reliability index for combined moment and axial force obtained using partial material strength
% reduction factors and L/D=0.5
% beta_PMr2=reliability index for combined moment and axial force obtained using partial material strength
% reduction factors and L/D=1.5
% beta_PMu1=reliability index for combined moment and axial force obtained using strength reduction factors
% in ACI 318-14 and L/D=0.5
% beta_PMu2=reliability index for combined moment and axial force obtained using strength reduction factors
% in ACI 318-14 and L/D=1.5
% beta_1=factor relating depth of equivalent rectangular compressive stress block to depth of neutral axis
% gamma=ratio of distance between outer layers of reinforcement in column to overall column depth
% epsilon_s1=strain in the 1st layer of reinforcement
% epsilon_s2=strain in the 2nd layer of reinforcement
% epsilon_s3=strain in the 3rd layer of reinforcement
% epsilon_s4=strain in the 4th layer of reinforcement
% epsilon_s5=strain in the 5th layer of reinforcement
% epsilon_y=yield strain of reinforcement
% angle_theta= angle theta, angle used to calculate compression segment of circular column
% mu_=mean of the associated normal distribution for lognormal distribution
% mu_=location parameter for Gumbel distribution
% rho_g=total reinforcement ratio, equal to ratio of total longitudinal reinforcement area to cross-
% sectional area of column
% sigma_=standard deviation of the associated normal distribution for lognormal distribution
% phi_sc=a pair of partial material strength reduction factors
% phiP_n=design axial strength in ACI 318-14 (kN)
