Abstract

Previously, pharmacological activation of Wnt-signaling in human bone marrow-derived multipotent stromal cells (hMSC) generated conditioned media (CM) that promoted β -cell regeneration in streptozotocin-treated mice. Ductal-derived endocrine progenitors, which have been shown to generate β -cells following pancreatic injury, represent a candidate for the ‘signal-receiving cell’. Ductal (CK19+) cells from mice pancreata obtained by purification of live Dolichos Biflorus Agglutinin lectin+ cells and cultured in minimal media supplemented with Untreated, Wnt-activated, or Wnt-inhibited CM demonstrated a significantly increased proportion of EdU+/CK19+ cells following 48-hours of supplementation but no endocrine phenotype acquisition. Lineage-tracing CK19-CreERT;Ai9(RCL-tdT) mice treated with tamoxifen (single dose) demonstrated specific labeling of pancreatic CK19+ cells. Streptozotocin treatment (60 mg/kg/day, 5 days) resulted in decreased β -cell mass, islet density, and insulin+ cell frequency, as well as impaired glucose tolerance and increased pancreatic leukocyte infiltration. This model will be used in future studies to lineage-trace CK19+ cell contribution during hMSC CM-induced islet regeneration.

Summary

Type 1 diabetes is characterized by the destruction of insulin-producing β -cells in pancreatic islets, leaving patients unable to control their blood glucose. Regeneration of lost β -cells represents a promising treatment strategy. Our lab pioneered the use of transplanted human bone-marrow derived mesenchymal stem cells (MSC) to stimulate islet regeneration in mice with β -cell destruction. Pharmacological activation of the Wnt-pathway in MSC cultures generated a concentrated protein mixture (CM) that consistently reduced blood glucose levels in mice with diabetes. However, the identity of signal-receiving cells that mediate islet regeneration within the pancreas remains unknown. Recently, regeneration of β -cells from pancreatic duct cells has been demonstrated. Treating isolated pancreatic duct cells with MSC CM increased their replication compared to minimal culture conditions but did not stimulate expression of other pancreatic cell proteins. We also characterized a specialized mouse model designed to follow the fate of duct cells. This model will be used in future studies to investigate ductal cell contribution to islet regeneration following CM injection. These studies contribute to the development of ‘cell-free’ regenerative medicine therapies for diabetes.

Co-Authorship Statement

The following contains material from a manuscript in preparation co-authored by Brianna Ananthan, Gillian Bell, Dr. Tyler Cooper, and Dr. David Hess. Brianna Ananthan performed all experimental work presented in this thesis in the lab of Dr. David Hess. Gillian Bell helped with animal care, experimental conceptualization, and technique training. Dr. Tyler Cooper assisted with experimental conceptualization. Dr. David Hess contributed to the design and interpretation of all experiments.

Acknowledgements

Firstly, I would like to express my deep appreciation for my supervisor, Dr. David Hess, for fostering a supportive lab environment and teaching me a multitude of valuable academic and life skills. From my start in the lab as a fourth-year student, your guidance and encouragement have increased my passion for science and research as a learner, collaborator, and community member. Thank you for your ongoing support and patience through the challenges and breakthroughs. The skills developed and lessons learned under your supervision will be ones that will stick with me for a lifetime.

I would like to thank the members of my advisory committee: Dr. Samuel Asfaha, Dr. Cheryle Séguin, and Dr. Lina Dagnino for your insight and technical expertise which helped advance my project every step of the way.

Thank you, Gillian Bell, for teaching me so many techniques from cell culture to animal care from the beginning. Your expertise and support were instrumental in my path as a graduate student. Your willingness to lend a helping hand at every step has been so inspirational.

I would like to thank all of the members of the Hess lab who provided insight and support throughout my thesis work, including Sarah Krause, Yehia Moharrem, Christopher Leclerc, Fiona Serack, and Dr. Tyler Cooper. I would also like to thank Sarah and Yehia for the many caffeine runs which helped me push through long days. Thank you to Kristin Chadwick at the London Regional Flow Cytometry Facility for her services in cell sorting and flow cytometry troubleshooting.

I would also like to thank Canadian Institutes of Health Research and the Juvenile Diabetes Research Foundation for providing funding for my work as a graduate student.

Finally, I would like to thank my family for their wisdom and emotional support throughout these two years. To my siblings, Jason, Meghan, Joshua, and Matthew, thank you for always listening and providing perspective through the ups and downs. To my partner, Jason, thank you for riding this rollercoaster with me with a big heart and open arms. To my parents, I cannot even begin to express my appreciation for the unconditional support you've given me over the years in all of my pursuits. I love you all.

List of Abbreviations

- 7-AAD – 7-Aminoactinomycin D
ADP – Adenosine diphosphate
ANOVA – Analysis of variance
APC – Adenomatous polyposis coli gene product
ARX – Aristaless related homeobox
ATP – Adenosine triphosphate
AUC – Area under the curve
AX - Alloxan
BB - Biobreeding
BSA – Bovine serum albumin
CAB – Citric acid buffer
CD – Cluster of differentiation
CK1 – Casein kinase 1
CK19 – Cytokeratin 19
CM – Conditioned media
DBA – Dolichos Bifluoros Agglutinin
DM – Diabetes mellitus
DMEM/F-12 - Dulbecco-s Modified Eagle Medium/Ham’s F-12
DMSO – Dimethyl sulfoxide
DNA-PK – DNA-dependent protein kinase
EdU – Ethynyldeoxyuridine
EGF – Epidermal growth factor
EMT – Epithelial-to-mesenchymal transition
Ezh2 - enhancer of zeste 2 polycomb repressive complex 2
FACS – Fluorescence activated cell sorting
FGF – Fibroblast growth factor
GIP – Glucose-dependent insulinotropic peptide
GLP – Glucagon-like peptide
GLUT – Glucose transporter
GPCR – G-protein coupled receptor

GSK3 β – Glycogen synthase kinase-3 β
hESC – Human embryonic stem cells
HFD – High-fat diet
HGF – Hepatocyte growth factor
HLA – Human leukocyte antigen
hMSC – Human multipotent stromal cells
Hnf1b – Hepatocyte nuclear factor 1 homeobox B
IDF – International Diabetes Federation
IFN- γ – Interferon- γ
IGF-1 – Insulin growth factor 1
IL-1 β – Interleukin 1 β
iPan – Intrapancreatic
iPSC – Induced pluripotent stem cells
IRS – Insulin receptor substrate
ISCT - International Society for Cellular Therapy
MAF - v-maf musculoaponeurotic fibrosarcoma oncogene homologue
MFI – Mean fluorescence intensity
MHC – Major histocompatibility complex
MSC – Multipotent stromal cells
NGF – Nerve growth factor
Ngn3 – Neurogenin 3
Nkx6.1 – NK6 homeobox 1
NOD – Non-obese diabetic
PAX – Paired box
PBS – Phosphate buffered saline
PDC – Pancreatic ductal cell
Pdgfr - platelet-derived growth factor receptor
PDX-1 – Pancreatic and duodenal homeobox 1
PERK – Pancreatic endoplasmic reticulum kinase
Pft1a – Pancreas-specific transcription factor
Polypeptide – PP

RNA-seq – Ribonucleic acid sequencing
ROS – Reactive oxidative species
SCID – Severe combined immunodeficient
SD – Standard deviation
SEM – Standard error of the mean
STZ - Streptozotocin
T1D – Type 1 diabetes
T2D – Type 2 diabetes
TCF/LEF – DNA-bound T-cell factor/lymphoid enhancer factor
Th – T helper
TNF- α – Tumor necrosis factor- α
VEGF – Vascular endothelial growth factor
Wnt+ - Wnt-stimulated
Wnt- - Wnt-inhibited

1.0 Introduction

1.1 Functions of the Pancreas

The pancreas, a digestive organ located in the upper left abdominal cavity, is composed of exocrine and endocrine tissue. Exocrine cells, including acinar and ductal cells, aid in the digestion of food passing from the stomach into the small intestine. Acinar cells synthesize proenzymes, which become activated in the duodenum to break down proteins, carbohydrates, and lipids. Ductal cells secrete bicarbonate to neutralize acidic chyme from the stomach as it passes into the duodenum. Endocrine cells, organized in clusters called islets of Langerhans, synthesize and secrete hormones via the portal vein system to regulate glucose homeostasis¹.

1.1.1 Human Pancreas Development

During human fetal development, the pancreas arises from interactions between the endodermal epithelium and surrounding mesenchyme². Pancreatic organogenesis begins with the formation of the pancreatic and duodenal homeobox 1 (Pdx1)- and pancreas-specific transcription factor (Ptf1a)-expressing dorsal and ventral buds from the endoderm-derived primitive gut epithelium at gestational day 26³⁻⁵. Subsequently, fusion of these buds forms the definitive pancreas with an interconnected ductal network³. As the left ventral bud regresses, later becoming the inferior head of the pancreas, the right ventral bud fuses with the dorsal bud during gut rotation at 6-7 weeks of gestation, giving rise to the majority of the pancreas⁴. Between gestational days 45 and 47, the pancreatic epithelium undergoes active growth, proliferation, and branching morphogenesis into the surrounding mesenchyme, controlled by NOTCH, fibroblast growth factor (FGF), and epidermal growth factor (EGF) signaling^{3,4}. Compartmentalization of the pancreatic tip and trunk occurs at around gestational week 7, with proacinar/tip cells expressing GATA4 and bipotent endocrine/ductal progenitor cells expressing *Sox9*, NK6 homeobox 1 (*Nkx6.1*), hepatocyte nuclear factor 1 homeobox B (*Hnf1b*), and *Pdx1*^{4,6,7}.

Exocrine tissue, comprised of acinar and ductal cells, makes up >95% of the pancreas⁸. Acinar-specific gene expression of digestive enzyme precursors and other factors mark a distinct commitment at around gestational weeks 11-15, including chymotrypsinogen, trypsinogen, protease, elastase 1, and subsequently amylase after gestational week 23⁴. Acinar cells are connected to ductal tissue through centroacinar cells/terminal duct cells⁸. Duct cells transport these pancreatic zymogens and secrete bicarbonate to neutralize gastric acid into the duodenum⁸. Continued expression of *Sox9* and *Hnf1b* and expression of differentiated ductal cell markers including cytokeratin 19 (CK19), carbonic anhydrase 1, mucin 1, and cystic fibrosis membrane conductance regulator mark ductal commitment from trunk progenitors at gestational week 11^{4,8}. However, it remains unclear whether differentiated ductal cells retain the ability to give rise to endocrine cells that bipotent trunk precursor cells possess.

The endocrine compartment, which makes up 2-3% of the pancreas, is composed of hormone-secreting cells including insulin-secreting β -cells (65-80%), glucagon-secreting α -cells (15-20%), somatostatin-secreting δ -cells (3-10%), polypeptide (PP)-secreting PP cells (3-5%), and ghrelin-secreting ϵ -cells (<1%)⁹⁻¹⁴. Transient expression of the transcription factor Neurogenin 3 (*Ngn3*) and paired box (PAX)6 expression mark commitment of bipotent trunk progenitors to an endocrine lineage fate^{3,10,15}. As endocrine cells commit to their specific lineages, each cell type expresses a unique set of transcription factors. When endocrine cells commit to an α -lineage, they express aristaless related homeobox (ARX) and glucagon, but not paired box 4 (PAX4) or PDX1¹⁵. On the other hand, β -cells express PDX1, NKX6.1, v-maf musculoaponeurotic fibrosarcoma oncogene homologue (MAF)A, PAX4, and insulin, but not ARX¹⁵. It is thought that reciprocal inhibition between ARX and PAX4 expression may mark a key checkpoint in specification between α - and β -cell identity, respectively¹⁶⁻¹⁹. The first endocrine cell type to appear is insulin-expressing cells at gestational week 7.5, followed by glucagon- and somatostatin-expressing cells⁴. Differentiated endocrine cells migrate away from the ductal epithelium and organize into clusters called islets of Langerhans which form during gestational week 10 and obtain a vascular network by gestational week 14^{4,8}. The majority of α -, β -, and δ -cells within the human pancreas are single hormone expressing after birth⁴. Bi-hormonal expression of insulin and glucagon in approximately 20-40% of α - and β -cells has been noted between gestational week 9 and 16, which significantly declined by gestational week 21 and was predominantly undetectable in the adult pancreas^{4,15}.

1.1.2 Glucose Homeostasis and Regulation of Insulin Secretion

The human body requires a consistent supply of glucose during all states: well-fed, starvation, exercise, rest, or stress²⁰. For example, the human brain requires 6 grams of glucose per hour to maintain basic function²⁰. The islets of Langerhans play a crucial role in maintaining normoglycemia through secretion of antagonistic hormones, insulin and glucagon, to prevent deleterious consequences of hyperglycemia and hypoglycemia. After a meal, absorption of carbohydrates causes blood glucose levels to rise. In response to elevated exogenous glucose concentrations, circulating blood glucose is taken up from capillaries within and surrounding islets by the low affinity facultative glucose transporter (GLUT) 2 ($K_m=17$ mmol/l), located on pancreatic β -cells^{14,21,22}. Upon entry into the cell, this glucose enters glycolysis to increase the ratio of adenosine triphosphate (ATP) to adenosine diphosphate (ADP)¹⁴. An increased ATP/ADP ratio leads to closure of ATP-sensitive potassium (K^+)-channels and subsequent depolarization of the β -cell membrane¹⁴. Upon depolarization, voltage-dependent calcium (Ca^{2+})-channels facilitate the influx of Ca^{2+} ions, which triggers fusion of insulin-containing vesicles with the plasma membrane and release of vesicle contents into the blood in a biphasic manner^{14,23}. Circulating insulin is taken up primarily by the liver, muscle, and adipose tissue to facilitate insulin-dependent uptake of exogenous glucose via GLUT4 from the blood, promoting anabolic processes such as glycogenesis and lipogenesis^{14,24-26}. Conversely, when blood glucose levels are low, such as during a fasting state, α -cells secrete glucagon which signals hepatocytes to mobilize glucose via glycogenolysis to restore normoglycemia.

Insulin secretion is affected by additional external regulators. Incretin hormones, including glucagon-like peptide (GLP)-1 and glucose-dependent insulinotropic peptide (GIP) amplify insulin secretion²⁷. GLP-1 and GIP are released by enteroendocrine L-cells and K-cells, respectively, following nutrient entry into the intestine following oral ingestion²⁸⁻³³. Pancreatic β -cells can increase the rate of insulin translation in response to the presence of nutrients, regulated in part by pancreatic endoplasmic reticulum kinase (PERK) and eukaryotic initiation factor 2a^{22,34-36}. Conversely, short-chain fatty acids exhibit an inhibitory effect on insulin secretion as a result of reduced ATP/ADP ratio following oxidation^{14,37}. The stress hormone norepinephrine also inhibits insulin secretion by binding to G-protein coupled receptor (GPCR)-linked α_2 -adrenergic receptors, causing hyperpolarization of β -cells³⁸⁻⁴⁰. Proper regulation of insulin secretion and

function is critical for energy homeostasis. β -cell dysfunction, a hallmark of diabetes mellitus (DM), leads to aberrant glucose homeostasis and long-term complications.

β -cell mass can be dynamic to meet bodily demands and maintain glucose homeostasis during pregnancy and weight gain. Studies have shown a linear correlation between β -cell mass and body weight and/or body mass index in mice, rats, and humans^{41–44}. β -cell mass is dictated by the balance between β -cell production (through replication or neogenesis), β -cell death, and β -cell volume changes (hypertrophy or atrophy)⁴⁴.

1.2 Diabetes Mellitus

The earliest known report of DM dates back to 1552 BC when Egyptian physician Hesy-Ra described a disease characterized by frequent urination and rapid weight loss⁴⁵. Between the fifth and sixth centuries, Sushrant recorded an association of these symptoms with sweet-tasting urine in Indian literature⁴⁶. Since then, the emergence of chemical analysis as a diagnostic tool and the study of endocrinology have improved our understanding of diabetes pathology⁴⁶.

Diabetes results from the destruction of insulin-producing β -cells in the pancreas as a consequence of autoimmune attack (Type 1) or insulin insensitivity (Type 2), leaving patients unable to control blood glucose⁴⁷. The International Diabetes Federation (IDF) the prevalence of diabetes in adults to be 463 million in 2019, which is projected to increase to 700 million by 2045⁴⁸. The annual economic burden of diabetes and its cardiovascular co-morbidities has been estimated at \$825 billion in a systematic review by the Non-communicable Diseases Risk Factor Collaboration⁴⁹. This load is placed on patients and their families, their health infrastructures, and national economies⁴⁹. *Thus, there exists an irrefutable need to develop curative therapies for diabetes.*

1.2.1 Type 1 Diabetes

Type 1 diabetes (T1D) is an autoimmune disease resulting in the selective destruction of pancreatic β -cells by T-lymphocytes²². Typically diagnosed in juvenile patients, T1D is characterized by the inability to synthesize and secrete insulin endogenously⁵⁰. The extent of β -

cell loss at the presentation of clinical symptoms varies between individuals and is dependent on age and cellular pattern of infiltrating cells during insulinitis⁵¹⁻⁵⁴. T1D accounts for <15% of total DM cases, with a worldwide prevalence of 1.1 million in children aged 0-19 in 2019^{48,55}. The worldwide incidence of T1D has been estimated to increase 3% annually, with the greatest increase observed in children aged 0-4⁵⁵.

Apoptosis of β -cells in T1D results from immune antibody binding and cellular reactivity to endogenous islet antigens. T-cell and macrophage islet infiltration and subsequent release of inflammatory cytokines, including interleukin-1 β (IL-1 β), interferon- γ (IFN- γ), and tumor necrosis factor- α (TNF- α), result in T-cell activation and β -cell destruction^{22,56-61}. Following autoantibody generation, cluster of differentiation (CD) 4+ naïve T helper (Th) 0 cells polarize towards an inflammatory Th1 phenotype. Th1 cells presented with islet self-antigens by antigen presenting cells promotes β -cell destruction through release of cytokines and subsequent recruitment of pro-inflammatory (M1) macrophages and CD8+ cytotoxic T-lymphocytes^{22,62-66}. Activated T-lymphocytes then mediate direct β -cell destruction through the pore-forming perforin-dependent pathway or induce apoptosis via Fas/Fas ligand interactions⁶⁷. Mutations in the human leukocyte antigen (HLA) gene, encoding cell surface antigens that facilitate interaction with immune cells, correlate to an increased risk in developing T1D⁶⁸⁻⁷⁰. Environmental factors including infant nutrition, vitamin D deficiency, gut microbiota, and viral infections may contribute to the development of T1D in individuals with genetic predispositions⁷¹. Our understanding of the underlying causes and progression of T1D is growing with use of advanced technologies including artificial intelligence, however, characterization of the disease in humans is complicated by the latency between the onset of the autoimmune disease process and presentation of clinical symptoms, as well as limited availability of human pancreas tissue for study⁷²⁻⁷⁴.

1.2.2 Type 2 Diabetes

Glucose homeostasis in the body depends on insulin secretion by pancreatic β -cells and normal body cell responses to insulin receptor binding and subsequent glucose uptake⁷⁵. During Type 2 diabetes (T2D) pathogenesis, the response to insulin becomes defective, leading to dysregulated glucose balance and metabolism. Of the 463 million people estimated to have diabetes by the IDF, individuals aged 20-79 with T2D overwhelmingly dominate this estimation⁴⁸.

Approximately 50% of adults living with diabetes are unaware of their condition because there is a long pre-detection period (3-7 years) during which blood glucose levels are elevated but symptoms are not clinically diagnosed^{48,55}. Thus, early detection is crucial in improving outcomes associated with T2D and associated complications^{48,55}. In developed countries, the annual incidence of T2D is estimated at 6.7-7 per 1000 individuals per year⁵⁵.

Also termed non-insulin-dependent diabetes, the development and progression of T2D is marked by deterioration in the ability to respond to elevated blood glucose levels over several years. Progression towards a diabetic state is characterized by a reduction in insulin sensitivity, leading to decreased glucose uptake by effector cells⁷⁶. When the energy balance in the body is chronically skewed towards excess calories, fat accumulates in subcutaneous tissue⁷⁷. When the storage capacity of this tissue is exceeded, fatty acids are stored in tissues such as the liver, muscles, and in the pancreas⁷⁷. Fat accumulation in liver and muscle tissue contributes to impaired glucose uptake in response to insulin as a result of impaired insulin receptor tyrosine kinase activity, while fat in the pancreas contributes to further β -cell dysregulation⁷⁷⁻⁷⁹. Studies suggest that this impaired insulin response also stems from dysfunctional glucose storage processes, including decreased skeletal muscle glycogenesis and increased gluconeogenesis despite hyperinsulinemia^{76,77,79}. Following initial insulin resistance, compensatory mechanisms in response to the increased metabolic load, including β -cell mass expansion and increased secretion of insulin by β -cells will occur but cannot be sustained over time^{77,80}. Chronic hyperglycemia depletes insulin-containing vesicles, reducing the capacity of β -cells to respond to new glucose. Glucotoxicity, which is correlated with an increase in reactive oxidative species (ROS), also causes stress on β -cells, subsequently leading to β -cell hypertrophy and increased risk of apoptosis⁸¹. As T2D progresses, the rate of β -cell apoptosis exceeds the rate of β -cell replication and neogenesis, leading to a decline in total β -cell mass⁸⁰.

Aberrant innate immunity activation also plays a role in the progression of T2D. Increased levels of circulating innate immune acute-phase circulating factors, including C-reactive protein, serum amyloid A, α -1-acid glycoprotein, sialic acid, and IL-6, have all been observed in T2D patients⁸². Increased circulating inflammatory cytokines can exacerbate insulin resistance. For example, TNF- α activates c-Jun NH₂-terminal kinase which inhibits insulin signaling through serine phosphorylation of insulin receptor substrate (IRS)-1 and IRS-2 and stimulation of suppressor of cytokine signaling proteins, which bind and facilitate degradation of IRS-1 and IRS-2⁸³.

Genetic predispositions also predict susceptibility to T2D. As a polygenic disease, in which single mutations can have protective or deleterious effects, scientists have been working to identify candidate genes to characterize the genetic components in patients with T2D⁸⁴. Single nucleotide polymorphisms in genes including peroxisome proliferator-activated receptor γ (PPARG), potassium inwardly rectifying channel subfamily J member 11 (KCNJ11), Wolfram syndrome 1 (WFS1) gene, and HNF1b are associated with development of T2D⁸⁴. In individuals with genetic predispositions, environmental factors including high-fat diet, reduced physical activity, age, pollutants, and exposure to a diabetic environment in utero contribute to an increased risk of T2D⁸⁵⁻⁸⁷. Consequences of chronic hyperglycemia and fat accumulation in organ tissues include cardiovascular disease, retinopathy, and neuropathy⁸⁸.

1.2.3 Animal Models to Study Diabetes

Animal models of diabetes allow for study of spontaneous or induced pathology that resembles one or more aspects of the disease in humans⁸⁹. Both T1D and T2D are multifactorial diseases in which polygenic and environmental components contribute to disease progression.

1.2.3.1 Models for T1D

To study autoimmune T1D, the non-obese diabetic (NOD) mouse is commonly used. In NOD mice, insulinitis starts at approximately 4-5 weeks of age with lymphocytes surrounding islets followed by infiltration of an unusually high number of CD4+ and CD8+ T-cells⁸⁹. Immune cell influx ultimately results in destruction of >90% of β -cells and hyperglycemia by weeks 24-30 of age⁸⁹. As in humans, NOD mice develop autoantibodies to insulin, glutamic acid decarboxylase, and the tyrosine phosphatase ICA512⁸⁹. Major histocompatibility complex (MHC) alleles are also important factors in disease progression in these mice, similar to humans⁸⁹. Although clinical symptoms typically present in human patients, including hyperglycemia, glycosuria, polydipsia, and polyuria, manifest in NOD mice, they have a higher resistance to ketoacidosis and can survive up to 2-4 weeks without exogenous insulin⁸⁹.

The Diabetes-prone biobreeding (BB) rat has MHC gene susceptibility to autoimmune diabetes and develops islet-specific and glutamic acid decarboxylase autoantibodies^{89,90}. Insulinitis within this rat model is similar to human pathogenesis with Th1-lymphocytes predominating infiltration⁹¹. At 8-16 weeks of age, rats become hyperglycemic, lack insulin, and exhibit polyuria and polydipsia⁸⁹. Similar to humans, BB rats are prone to ketoacidosis and need exogenous insulin treatments to survive⁹¹. However, this rat model has depressed levels of CD4+ T-cells and almost non-existent CD8+ T-cells⁹¹, which compromises its acceptability as a model for human T1D diabetes.

Chemical agents have also been used to model diabetes. Streptozotocin (STZ) and alloxan (AX) target pancreatic β -cells via GLUT2 transporter specificity and mediate β -cell death through ROS and free radical mechanisms⁸⁹. STZ, a nitrosourea related antibiotic and antineoplastic agent produced by *Streptomyces achromogenes*, induces DNA alkylation and fragmentation within β -

cells, leading to β -cell destruction and insulin-dependent diabetes⁸⁹. Although these chemical agents cause hyperglycemia and insulinopenia, they do not recapitulate the autoimmune aspects of T1D^{89,92-94}.

1.2.3.2 Models for T2D

Spontaneous mouse models of T2D contain genetic mutations that make mice susceptible to the development of diabetic-like symptoms. Among these are the ob/ob and db/db mouse strains with mutations in the leptin and leptin receptor genes, respectively⁸⁹. The ob/ob genotype is characterized by excessive appetite, low energy expenditure, and obesity starting at approximately 4 weeks of age⁸⁹. Following insulin resistance from hyperphagia and obesity, hyperinsulinemia ensues^{89,95}. Ob/ob mice derived from the C57BL/6J strain develop mild hyperglycemia, while similar mice derived from the C57BL/KS strain develop severe diabetes which may be lethal^{89,95}. Db/Db mice also develop hyperphagia, obesity, insulin resistance, and hyperinsulinemia before developing hyperglycemia by 8 weeks of age as a result of β -cell failure^{89,96}.

Non-spontaneous models of T2D include C57BL/6J mice fed a high-fat diet (HFD). HFD induces system metabolic alterations consistent with T2D. Disease progression is marked by obesity, insulin resistance, subsequent hyperglycemia, and lipid accumulation⁹⁷. ROS production as a result of chronic hyperglycemia causes apoptosis of β -cells and subsequent reduction in β -cell mass^{98,99}. Mice fed a HFD also exhibit increased systolic blood pressure compared to those fed a low-fat diet¹⁰⁰. Similar to human T2D pathogenesis, low level chronic inflammation, including within the cardiovascular system, has been identified in HFD mice, which has been attributed to immune responses that are more often Th1-mediated⁹⁹. However, a standardized protocol for this model has yet to be established.

1.3 Therapeutic Approaches to Treat Diabetes Mellitus

Scientific and technological advances have played a critical role in developing effective treatments for diabetes. Identifying targets and strategies for long term, sustainable treatments has been crucial in the advancement of patient care. Treatments for diabetes have primarily focused on insulin therapy, gene therapy, cell replacement, and regenerative approaches. Before these treatments became available, physicians promoted fasting and calorie-restricted diets for diabetes to improve glucosuria and acidosis, and delay negative outcomes in children with diabetes^{101,102}. Starting with the discovery of insulin in 1920, finding a curative therapy for diabetes has seemed more within reach¹⁰².

1.3.1 Drug Treatments

Exogenous insulin therapy has become a common treatment for patients with T1D and for some with T2D. In 1920, Frederick Banting, an orthopedic surgeon, had the idea to isolate pancreas extracts to treat depancreatized dogs that developed diabetes¹⁰². Following intravenous injection of what Banting and Charles Best termed ‘isletin’, the blood glucose levels of these dogs decreased¹⁰². After J.B. Collip joined the group in 1921, the team purified isletin for human use, and the first injection was given to a 14-year-old boy in 1922¹⁰². Improvements in methodology for purification over the ensuing years has led to consistent positive clinical outcomes. Subsequent development of more potent insulin and short- and long-acting analogs, has led to improved physiological control of diabetes symptoms and reduced complications¹⁰². Today, insulin therapy is given through injections or via an insulin pump and can either be used alone or alongside other oral medications to control symptoms. There are many different types of exogenous insulin available with differing pharmacokinetic properties, as well as various delivery methods, so finding the most suitable therapy for each patient is paramount in maintaining their health. However, patients on insulin therapy must continuously monitor their blood glucose and injections must be given on a regular basis lifelong.

Other pharmacological agents and combination therapies have also been used to control blood glucose and other symptoms in patients with diabetes. Metformin is a biguanide that increases insulin sensitivity by phosphorylating GLUT-enhancer factors and inhibits hepatic gluconeogenesis^{103,104}. Additionally, in combination with an effective treatment plan, metformin has been shown to help with weight loss as well as serum triglyceride and low density lipoprotein level reduction¹⁰⁵. However, it does not affect the activity of β -cells. Sulfonylureas act on the ATP-sensitive potassium channels of β -cells to trigger insulin secretion¹⁰⁶. Efficacy of sulfonylureas require the presence of residual β -cell mass and may contribute to exhaustion and death of those remaining β -cells¹⁰³. While there has been tremendous progress in developing pharmacological therapies to manage diabetes, they cannot fully recapitulate the refined and complex processes of blood glucose homeostasis in healthy persons. Moreover, the cost of medication for patients represents a major hurdle for adherence to treatment¹⁰⁷.

1.3.2 Gene Therapy

Gene therapy refers to the replacement or silencing of dysfunctional genes to treat or prevent disease. Gene vectors in the form of lentiviruses, adenoviruses, liposomes, and naked DNA have been used for delivery of the insulin gene into various body tissues, including pancreatic, liver, fat, and muscle¹⁰³. One genetic approach to delay the progression of autoimmune diabetes and destruction of β -cells targets the immune system itself. Inducing expression of proinsulin under control of the MHC class II promoter has been shown to prevent onset of T1D in NOD mice¹⁰⁸. However, this strategy relies on early detection of immune reactivity to β -cells before clinical presentation of symptoms.

Another gene therapy approach has been the reprogramming of non- β -cells to replace lost β -cells through induced expression of β -cell specific transcription factors. For example, recombinant-adenovirus-mediated gene transfer of Pdx-1 to hepatocytes of STZ-treated mice considerably increased biologically active plasma insulin content and reduced hyperglycemia¹⁰⁹. Pdx-1 is a crucial regulator in early pancreas morphogenesis and plays an important role in controlling glucose-dependent insulin expression in β -cells¹¹⁰. Reprogramming of pancreatic cells has also shown some success in recovering β -cell mass. *In vivo* delivery of adenoviral vectors carrying Ngn3, Pdx1, and MafA preferentially reprogrammed pancreatic exocrine cells into β -like

cells with indistinguishable morphology and gene expression from endogenous β -cells that could ameliorate STZ-induced hyperglycemia¹¹¹. Pdx1 and MafA-carrying adeno-associated virus cassettes administered through the pancreatic duct reprogrammed α -cells into insulin-expressing β -cells to restore normoglycemia in in AX-treated or autoimmune NOD mice¹¹². However, long-term effectiveness of cell reprogramming would have to be combined with treatment strategies to combat ongoing autoimmunity or increased metabolic load to improve survival of newly formed β -cells.

1.3.3 Cell Replacement Strategies

In 2000, James Shapiro and his team published their success in helping seven consecutive patients with T1D achieve insulin independence a year after islet transplantation via the Edmonton Protocol combined with glucocorticoid-free immunosuppressive therapy to reduce chances of graft rejection¹¹³. Islets isolated from multiple cadaveric donors matched for blood type and lymphocytotoxic antibodies were transplanted to recipients via the hepatic portal vein¹¹³. The immunosuppressive regimen included long-term sirolimus and tacrolimus use in combination with short-term dacluzimab administration¹¹³. However, ongoing autoimmunity, graft rejection, and adverse responses to immunosuppressive drugs ultimately contributed to rejection of donor islets^{114,115}. Since then, intensive research has focused on improving outcomes and graft survival for patients who have received islet transplants. Data from the Collaborative Islet Transplantation Registry indicates a 44% success rate in achieving insulin independence 3 years after surgery¹¹⁶. While there have been positive results in the field of allogeneic islet replacement therapy in controlling blood glucose and improving glycated hemoglobin levels in diabetic patients via the Edmonton Protocol¹¹³, shortages of cadaveric donor islets¹¹⁷⁻¹¹⁹, the necessity for lifelong immunosuppressive drugs¹¹⁷⁻¹²¹, and modest success achieving long-term insulin independence^{118,120} have proven to be major barriers to this treatment strategy.

To address the challenge of donor tissue availability, scientists have investigated alternate sources of β -cells for transplantation. One attractive source under investigation is pluripotent stem cells, including human embryonic stem cells (hESC) or induced pluripotent stem cells (iPSC). hESC, first derived from the inner cell mass of blastocysts by James Thomson and his team in 1998, can give rise to any cell type found in the body when given the appropriate signals^{116,122}. iPSC, first described by Shinya Yamanaka in 2006, are reprogrammed adult fibroblast or somatic cells that have been reverted to a pluripotent state through introduction of factors including the transcription factors Oct3/4, Sox2, c-Myc, and Klf4 in culture^{116,123}. Under stepwise differentiation protocols, iPSC can be pushed towards a β -cell lineage that express maturity markers (e.g. insulin, MafA, Nkx6.1, Pdx1) through guidance following developmental specification^{124–128}. However, of the differentiated endocrine cells generated in culture, many are polyhormonal and lack glucose-dependent insulin secretory ability¹¹⁶. These cultures also contain other pancreatic cell types from various developmental stages¹¹⁶. While there has been success in reducing hyperglycemia in mice with chemically ablated β -cells, challenges in the application of this approach in clinical trials include immune response towards the encapsulation device^{129,130}, hypoxia following implantation^{129–132}, and impaired insulin release kinetics¹³². Ongoing research focussed on more efficient generation of insulin-producing β -like cells and encapsulation strategies to promote survival have been undertaken by companies such as Semma Therapeutics and ViaCyte¹³³.

1.3.4 Endogenous Regeneration of β -cells

Another strategy under investigation to restore β -cell mass focuses improvement of the microenvironment that causes β -cell death. Normally, the adult pancreas exhibits low rates of cell turnover and limited response to injury compared to other organs such as the liver or small intestine^{134–136}. However, increased β -cell mass in response to pregnancy or obesity suggests that the endocrine pancreas may be stimulated to heal under diabetic conditions in the presence of a microenvironment that favours regeneration over destruction^{134,137,138}.

One method has targeted regulation of pathways that affect β -cell proliferation. Early in life, the primary mechanism of β -cell expansion is through self-replication^{139,140}. However, the proliferative capacity of β -cells declines in an age-dependent manner with negligible detectable

levels in adults over 30 years old¹⁴¹. One goal within this field is to identify key regulators of β -cell proliferation that mediate this observed decrease in proliferation over time. An increase in expression of p16^{Ink4a}, a cyclin-dependent kinase inhibitor encoded by the *Cdkn2a* gene, in β -cells is strongly correlated with increased age^{118,142}. P16^{Ink4a} expression is inhibited by the epigenetic regulator histone-lysine N/methyltransferase enzyme encoded by enhancer of zeste 2 polycomb repressive complex 2 (Ezh2), which decreases its expression with age¹⁴³. Increasing Ezh2 expression in a transgenic mouse model through direct upregulation or by indirectly targeting platelet-derived growth factor receptor (Pdgfr) signaling has shown success in achieving β -cell mass expansion through replication^{143,144}. However, translation of findings in regulation of cell cycle proteins in humans is difficult, as cell-cycle proteins in rodent islets are different from those identified in human islets. High-throughput screens have identified compounds that can stimulate β -cell proliferation in human islets such as 5-iodotubercidin, harmine, and WS6^{145–147}. While there has been progress in elucidating β -cell regulatory pathways and identifying stimulators of proliferation, clinically relevant β -cell mass restoration by β -cell replication alone has proven difficult to attain^{136,148}.

Another strategy to stimulate β -cell regeneration focusses on conversion of non- β -cells to β -cells *in situ*. Single-cell ribonucleic acid sequencing (RNA-seq) of human pancreata has revealed heterogeneity within cell populations with indication of intermediate stages between lineages, which could indicate potential plasticity within the human pancreas^{149–152}. Investigation of this potential plasticity has been conducted by the Collombat, Herrera, and Bonner-Weir groups, among others^{18,19,44,153–160}. Differentiation studies demonstrated induction of islet-derived fibroblast-like cells to hormone-expressing cells *in vitro* and transition between α - and β -cells following induction of lineage specific transcription factors in mouse models, suggesting previously unrecognized plasticity between mature endocrine cell types^{16,18,19,159,161}. Expression of MafA and Pdx1 in Nng3⁺/glucagon⁺ cells resulted in their transition to β -cells in transgenic mice¹⁵⁹. Following *Pax4*-mediated α - to β -cell transition, *Hnf1 β* ⁺ duct-lining cells demonstrated transient activation of *Neurogenin 3*, an endocrine progenitor marker, before adopting an α - then β -cell phenotype and function^{19,154,156}. Misexpression of Ngn3 in ductal cells stimulated reactivation of the endocrine lineage specification pathway, resulting in their transition into functional β -like cells in mice¹⁵⁴. Supporting the hypothesis that β -cells can be generated from

ductal cells in the adult pancreas, 15% of insulin-expressing β -cells, which were not associated with other islet cells, have been found in or budding from ductules, paralleling β -cell lineage specification processes in the developing pancreas¹⁶². *These findings have generated interest in stimulating islet regeneration during diabetes if we can identify clinically relevant stimuli to modulate these regulatory pathways.* While Ben-Othman *et al.* reported that long term gamma-aminobutyric acid exposure¹⁵⁵ and Li *et al.* reported artemether¹⁶³ could modestly induce α - to β -cell transition, subsequent studies have failed to replicate their results^{164,165}.

1.4 Multipotent Stromal Cells

Stem and progenitor cells from various lineages have been highly studied as a promising source of therapeutic properties. Multipotent stromal cells (MSC), also referred to as mesenchymal stem cells, have received a high degree of attention in recent years due to their wide range of therapeutic actions. The first descriptions of MSC appeared in the 1970s by Friedenstein and his team¹⁶⁶. Since then, investigation into the therapeutic potential of MSC has been of high interest based on their multipotency, secretory, and immunomodulatory functions. Derived from various sources within the body, MSC have been considered for therapies for a wide array of diseases including myocardial infarction, liver fibrosis, osteoarthritis, and diabetes, among others.

1.4.1 Properties and Characterization

The clear definition and criteria of MSC has long been debated. Many investigators have reported different methods for isolation, expansion in culture, and criteria for characterizing MSC, making comparison and applications of studies in different contexts difficult¹⁶⁷. In response, the International Society for Cellular Therapy (ISCT) published their minimal criteria for defining MSC in 2006¹⁶⁷. Their criteria include: plastic adherence; expression of cell surface markers CD105, CD73, and CD90 in $\geq 95\%$ of cells in culture, as well as negative expression of CD45, CD34, CD14, CD11b, CD19 and HLA isotype DR in $\leq 2\%$ of cells; and the capacity to differentiate into bone, fat, and cartilage *in vitro*¹⁶⁷. MSC can be isolated from various human adult tissues, including bone marrow^{168–170}, adipose tissue^{169,171}, peripheral blood^{172,173}, lung tissue^{174,175}, and muscle tissue^{176,177}. In response to the various tissue sources from which MSC can be derived, the ISCT recommended that descriptions of MSC be supplemented by the tissue origin as cells

from different tissues exhibit varied phenotype, functions, and secretory profiles¹⁷⁸. For example, expression of Sox2, a marker associated with the maintenance of multipotency, self-renewal, and neurogenesis in early embryonic development, has only been associated with MSC derived from bone marrow¹⁷⁹. MSC are highly proliferative *in vitro*, and those isolated from human bone marrow have been shown to maintain expression of the stem cell markers *Oct-4*, *Rex-1*, and *Sox-2* for at least 10 passages¹⁷⁷. However, differences in MSC properties are donor dependent. Among different bone marrow donors of varying ages, there are differences in growth kinetics, osteogenesis, alkaline phosphatase activity, and secretory profiles¹⁸⁰⁻¹⁸³. With donor and tissue source variability, research geared towards more thorough characterization of MSC, including cell subpopulations, is ongoing.

1.4.2 MSC-Mediated Repair

MSC have shown great promise as a therapeutic tool for a wide range of diseases and disorders. As previously mentioned, one of the criteria for defining MSC is their multipotency. When MSC are placed in induction medias supplemented with specific factors, they can be pushed down osteogenic, chondrogenic, or adipogenic lineages, which has stimulated interest in tissue replacement strategies¹⁸⁴⁻¹⁸⁶. While these cells possess the capacity for *in vitro* multipotency under appropriate culture conditions, *in vivo* engraftment studies have been largely disappointing¹⁸⁷⁻¹⁸⁹.

The benefits of MSC cell treatments have predominantly been attributed to indirect or paracrine mechanisms. MSC secrete a wide array of factors into the surrounding environment. The MSC secretome, which can be concentrated to generate conditioned media (CM), is comprised of soluble factors and extracellular vesicles, which together make up a regenerative microenvironment containing immunomodulatory, anti-apoptotic, pro-angiogenic, proliferative, and growth factors that facilitate tissue repair^{187,190-192}. Important for tissue regeneration, the secretome has been shown to include anti-apoptotic growth factors including insulin-like growth factor 1 (IGF-1), tissue inhibitor of metalloproteinases 1 and 2, growth hormone, EGF, hepatocyte growth factor (HGF), and nerve growth factor (NGF)¹⁸⁰. Immunomodulatory functions of MSC include promotion of a pro-regenerative macrophage phenotype, mobilization of macrophages to the site of injury, limiting degranulation of mast cells, inhibition of lymphocyte proliferation, decreasing lymphocyte proinflammatory cytokine synthesis, and increasing lymphocyte anti-

inflammatory cytokine synthesis¹⁸⁰. MSC secrete vascular endothelial growth factor (VEGF) which stimulates migration and proliferation of endothelial cells to facilitate the formation of blood vessels^{180,193,194}. Treatment using MSC CM has demonstrated regenerative effects in disease models including intervertebral disc injury, myocardial infarction, and neuronal damage in a preclinical setting, and bone regeneration and alopecia in clinical trials¹⁹⁵. Key advantages of this approach include: (1) avoidance of immune incompatibility and tumorigenicity associated with stem cell administration, (2) MSC CM can be assessed for efficacy, safety, and dosage similarly to other pharmaceuticals, and (3) MSC CM can be stored long term without compromising effectiveness¹⁸⁷. Use of CM also provides the opportunity to engineer production of specific factors through modulation of signaling pathways.

1.4.3 MSC as a Therapeutic Option for Diabetes

As documented in other tissues, MSC may have the ability to facilitate regeneration of pancreatic endocrine tissue. MSC isolated from human bone marrow have been shown to reduce hyperglycemia, increase serum insulin, and stimulate islet regeneration following intravenous injection or intracardiac infusion in STZ-treated mice¹⁹⁶⁻²⁰⁰. The immunomodulatory functions of MSC have also been shown to delay the onset of hyperglycemia and β -cell loss in mouse models of T1D²⁰¹. Intravenous injection of bone marrow-derived human MSC (hMSC) also improved blood glucose levels and ameliorated insulin resistance by increasing GLUT4 expression in a rat model of T2D²⁰². However, the mechanisms that mediate these therapeutic actions remain unclear. While focusing on the transdifferentiation potential of MSC initially sparked optimism in generating insulin-producing cells, low transdifferentiation efficiency and engraftment rates have limited clinical feasibility exploiting this uncommon property²⁰³. Thus, many current studies investigating the therapeutic abilities of MSC for treating diabetes focus on paracrine factors. Paracrine factors secreted by MSC have been shown to modulate β -cell signalling pathways to promote survival and improve glucose-dependent insulin secretion²⁰⁴⁻²⁰⁶.

Clinical trials using MSC to treat diabetes have focused primarily on harnessing their immunomodulatory properties. Clinically, these cells are an attractive therapeutic option because they can be isolated relatively non-invasively from various adult tissues including bone marrow and adipose tissue, or from perinatal tissues often discarded, such as the umbilical cord or placenta.

Additionally, their rapid expansion *in vitro* without significant loss in secretory regenerative ability add to their clinical applicability²⁰³. A number of these studies resulted in reduced insulin requirement, increased fasting C-peptide levels, and/or improved HbA1c with few reports of adverse events following transplantation into patients²⁰³. Some studies have also shown improvement of donor islet graft survival when transplanted in combination with MSC²⁰³.

We have previously shown that transplantation of culture-expanded bone marrow-derived hMSC also demonstrated the capacity to reduce hyperglycemia and increase β -cell mass by stimulating the formation of small ductal-associated islet clusters via paracrine signals in mice with STZ-mediated β -cell ablation^{198–200}. The modest short-lived increase in β -cell replication could not account for the robust increase in β -cell mass^{199,200,207}. However, regenerative capacity was donor-dependent^{199,200,208,209} and decreased with prolonged expansion^{199,200}. Comparative global secretome analyses by mass spectrometry revealed regenerative hMSC (hMSC^R) exclusively secreted proteins associated with active canonical Wnt/ β -catenin signaling, a pathway implicated in cell growth, proliferation, and differentiation²⁰⁸. In contrast, non-regenerative secretome samples (hMSC^{NR}) contained increased levels of Wnt-pathway inhibitors Dickkopf-1/3²⁰⁸.

The canonical Wnt/ β -catenin signaling pathway has various functions in embryonic development and adult homeostasis, including involvement in cell proliferation, polarity, and differentiation²¹⁰. The primary role of this pathway is to regulate nuclear levels of the transcriptional co-activator β -catenin. In the absence of signaling ligands, cytoplasmic β -catenin is constantly degraded by a destruction complex comprised of Axin, adenomatous polyposis coli gene product (APC), casein kinase 1 (CK1), and glycogen synthase kinase 3 (GSK3)²¹⁰. CK1 and GSK3 phosphorylate β -catenin for ubiquitination and degradation by proteasomes²¹⁰. This effectively prevents β -catenin from reaching the nucleus and target genes are repressed by the DNA-bound T cell factor/lymphoid enhancer factor (TCF/LEF) protein family²¹⁰. On the other hand, activation of this pathway is achieved when a Wnt ligand binds to a Frizzled receptor and co-receptor, low-density lipoprotein receptor related protein 6/5²¹⁰. Subsequent recruitment of Dishevelled results in inhibition of the aforementioned destruction complex, preventing phosphorylation of β -catenin²¹⁰. Cytosolic β -catenin accumulates and travels to the nucleus where it interacts with TCF/LEF proteins to activate expression of target genes²¹⁰. Apart from its

signalling functions, β -catenin also plays an important role in cell-cell adhesions²¹¹. To assess the relevance of the Wnt-pathway to the regenerative capacity of hMSC, Wnt-pathway activation was mimicked in hMSC^{NR} cultures using treatment with the glycogen synthase kinase-3 β inhibitor CHIR99021 for 24 hours in serum-free media before CM collection and concentration^{207,208}. In the absence of Wnt ligands, GSK3 marks β -catenin for degradation²¹² (**Fig. 1.1**). Conversely, Wnt-pathway inhibition was achieved using IWR-1, which stabilizes Axin in the β -catenin inhibition complex and ultimately facilitates its degradation^{213,214}.

Figure 1.1 CHIR99021 and IWR-1 can be used to stimulate or inhibit the canonical Wnt/ β -catenin pathway, respectively. When Wnt ligands bind to their appropriate Frizzled family receptor on the plasma membrane, an intracellular signal causes destabilization of the glycogen synthase kinase-3 β (GSK3)/Axin/Adenomatous Polyposis Coli (APC) inhibition complex, preventing the ubiquitination and degradation of cytosolic β -catenin and permitting its translocation into the nucleus to affect transcription of genes involved in cell growth, proliferation, and differentiation. CHIR99021, a GSK3 inhibitor, activates the Wnt pathway by destabilizing the GSK3/Axin/APC inhibition complex, and facilitating nuclear translocation of β -catenin. IWR-1 stabilizes Axin, and by extension the GSK3/Axin/APC inhibition complex, to promote ubiquitination and degradation of cytosolic β -catenin.

When co-cultured with human islets for 7 days, Wnt-stimulated (Wnt+) CM enhanced β -cell survival and proliferation compared to Untreated CM or basal Roswell Park Memorial Institute media²⁰⁸. After injection into the pancreas of STZ-treated mice, Wnt+ CM consistently induced reversal of hyperglycemia, increased β -cell mass, and improved glucose tolerance compared to unconditioned media or Wnt-inhibited (Wnt-) CM injection following intrapancreatic (iPan) injection in STZ-treated mice²⁰⁷.

While iPan-injection of *Wnt+ hMSC CM reliably rescues hyperglycemia and β -cell mass*, the identity of 'signal-receiving cells' within the pancreas that mediate islet regeneration remains unknown. Elucidation of the islet regenerative pathway and identification of the essential effectors that stimulate β -cell mass recovery will provide the foundation for a testable cell-free therapy and delivery method to reliably induce β -cell regeneration. hMSC^R CM contains pro-angiogenic factors, including FGF7, PDGF, and VEGF-A, which could produce a regenerative microenvironment that promotes islet vascularization²⁰⁸. Additionally, hMSC^R secrete immunomodulatory factors, including TGF- β and stromal cell-derived factor 1 (CXCL12), compared to hMSC^{NR}, which secrete elevated levels of pro-inflammatory cytokines, including IL-1 β , IL-6, and IL-8²⁰⁸. Collectively, iPan injection of Wnt+ hMSC CM creates a microenvironment that accelerates islet regeneration through its immunomodulatory, anti-apoptotic, pro-angiogenic, proliferative, and growth factors that facilitate tissue repair^{187,190–192}. Proteomic analyses and RNA-sequencing of hMSC CM may prove to be useful tools in elucidating the key factors that differentiate regenerative versus non-regenerative samples. Treatment efficacy in strong pre-clinical models, including NOD mice or db/db mice, will direct future studies in clinical trials.

1.4.4 Elucidating the Islet Regenerative Cascade Induced by hMSC CM

Analyses of human pancreas donations from healthy and diabetic individuals have revealed that insulin-expressing cells budding from pancreatic ducts was more common than observation of enlarged islets, indicating more putative regions suggesting neogenesis compared to areas of β -cell replication or hypertrophy^{43,44,215}. Additionally, expansion of islet-depleted ductal tissue *in vitro* in 3D Matrigel resulted in glucose responsive insulin secreting islet-like clusters budding from ductal clusters^{160,216}. Lineage tracing studies have demonstrated transition of duct cells to functional β -like cells following transcription factor misexpression, β -cell ablation, or pancreatic

injury^{153,154,156,217,218}. This proposed model suggests that ductal cells may act as facultative progenitors that contribute to β -cell neogenesis upon experience of stressful conditions. Following a dedifferentiation event including epithelial-to-mesenchymal transition (EMT) and transient re-expression of *Ngn3*, it is proposed that these cells transition to an α -cell phenotype before transitioning to β -like cells^{153,154,156,217} (**Fig. 1.2**). Additionally, the Medalist Study, which followed 411 patients with T1D for ≥ 50 years, showed that 63.4% had C-peptide levels within the minimal or sustained range²¹⁹. Furthermore, during a mixed-meal tolerance test, over half of individuals with C-peptide levels >0.17 nmol/l responded with a two-fold or greater increase compared to fasting levels²¹⁹. Histological analyses of pancreatic sections from individuals who had passed away during the course of the study revealed steady state insulin+ β -cell proliferation²¹⁹. These data support residual β -cell function in patients who have had T1D long-term. Thus, β -cell regeneration may be mediated by multiple cell populations, including pre-existing β -cells and facultative progenitors within the pancreas.

Following iPan injection, Wnt+ hMSC CM induced a regenerative cascade resulting in the emergence of neoislets associated with the ductal epithelium 4 days post-transplantation²⁰⁷. Histological analyses revealed detection of glucagon+ cells co-localized with β -cell markers insulin, MafA, or Nkx6.1²⁰⁷. Nuclear expression of Nkx6.1 and MafA in newly formed insulin+ islets suggested proper β -cell maturation²⁰⁷. Additionally, vimentin+ cell hyperplasia surrounding the ductal epithelium was observed following STZ-treatment with or without subsequent hMSC CM injection, which is consistent with a model of EMT by the ductal epithelium proposed by other groups^{156,207,220}. However, the rate of β -cell proliferation could not account for the robust increase in β -cell mass. To address the question of whether these neoislets originate from ductal facultative progenitors following Wnt+ CM injection, we proposed to use a lineage tracing mouse model to follow the fate of pancreatic CK19-expressing ductal cells.

These lineage tracing mice have a Cre recombinase fused to a murine estrogen receptor ligand binding domain inserted upstream of the initiation sequence of the CK19 gene²²¹. Expression of CK19, an intermediate filament protein, can be seen in the adult lung, oral cavity, stomach, small intestines, and within the pancreatic, renal, and hepatic ducts²²¹. Following administration of tamoxifen, which binds to the fused estrogen receptor, Cre recombinase can

access the nuclear compartment of cells to facilitate excision of the loxP-flanked STOP cassette flanking the Gt(ROSA)26SOR locus^{221,222}. This permits robust tdTomato fluorescence in cells that express CK19, permanently labeling these cells²²². This allows for fate-mapping of CK19-expressing cells through hMSC CM-induced islet regeneration to investigate their contribution to the new β -cell population.

Figure 1.2 Proposed mechanism for islet cell regeneration in hyperglycemic mice following Wnt+ hMSC CM iPan injection. We hypothesize iPan injection of Wnt+ hMSC CM will stimulate β -cell regeneration from ductal derived facultative precursors following EMT in hyperglycemic mice.

1.5 Hypothesis and Objectives

The overall objective of my thesis was to develop and characterize a model for assessing the contribution of CK19-expressing pancreatic duct cells in hMSC Wnt+ CM induced islet regeneration.

Based on the recent recognition of islet cell plasticity, we hypothesized Wnt+ hMSC CM would stimulate β -cell regeneration from ductal-derived precursor cells after direct injection into the pancreas of hyperglycemic mice.

To address this, the following aims were proposed:

- (1) To compare the regenerative functions of hMSC CM on isolated CK19-expressing ductal cells *in vitro*.
- (2) To characterize a lineage tracing model to assess the contribution of CK19+ ductal cells in islet regenerative mechanisms induced by hMSC CM.

2.0 Cytokeratin 19-expressing cells as a potential target for islet regeneration

2.1 Introduction

Allogeneic bone marrow transplantation is used to treat hematological cancers, including acute myeloid leukemia, to replace unhealthy, cancerous stem cells with healthy ones that regenerate the blood system²²³. The human bone marrow also hMSC, commonly referred to as mesenchymal stem/progenitor cells, that serve as long-term precursors for bone, cartilage, fat, and muscle cells²²⁴. Aside from the support of the self-renewing properties of hematopoietic progenitor cells in the bone marrow, MSC also secrete immunomodulatory, anti-apoptotic, pro-angiogenic, proliferative, and growth factors^{187,190–192}. The pioneering work by Hess *et al.*¹⁹⁸ has shown that transplantation of bone marrow-derived progenitor cells of hematopoietic and mesenchymal lineages improved serum insulin levels and reduced hyperglycemia via paracrine mechanisms in STZ-treated mice^{199,200,207,225,226}. Follow-up studies have supported the regenerative paracrine properties of bone marrow-derived hematopoietic and mesenchymal progenitor cell subtypes that stimulate β -cell proliferation or neoislet formation, respectively^{199,200}. Circumventing the complications of cellular transplantation, intrapancreatic injection of human bone marrow-derived MSC CM has also shown the potential to stimulate islet regeneration and rescue hyperglycemia in STZ-treated mice²⁰⁷.

Diabetes, which is associated with autoimmune β -cell attack (T1D) or insulin resistance resulting in β -cell dysfunction (T2D), results in β -cell destruction leaving patients unable to control blood glucose levels. With the prevalence of diabetes steadily rising⁴⁸, and the occurrence of severe cardiovascular comorbidities associated with hyperglycemia, investigation into novel curative therapies to rescue β -cell mass in patients with T1D and late-stage T2D is highly sought. Currently, reduced serum insulin and hyperglycemia are treated with exogenous insulin administration and other pharmacological agents to improve glycemic control¹⁰³. However, these treatments do not recapitulate the fine-tuned physiological responses set in motion following nutrient intake and patients remain at risk for extreme peaks and troughs in blood glucose levels. Consequently, comorbidities are highly prevalent in patients with T2D (>95%), the most common of which are severe cardiovascular complications including hypertension, critical limb ischemia, heart attack, and stroke²²⁷. While islet replacement strategies via the Edmonton Protocol have shown promise in helping patients control blood glucose¹¹³, shortages of donor tissue^{117–119}, the necessity for lifelong immunosuppressive drugs^{117–121}, and compromised long-term success islet survival and

sustaining insulin secretion^{118,120} remain major for islet transplantation. However, β -cell mass expansion during pregnancy and obesity suggests β -cells can either proliferate *in situ* or differentiate from progenitor cells upon the generation of a regenerative microenvironment^{228,229}. Identification of pathways that regulate β -cell proliferation and/or neogenesis is highly sought in regenerating β -cell mass. While β -cell proliferation is the primary driver of neonatal β -cell expansion, the proliferative capacity of adult β -cells sharply declines with age¹⁴¹. Although targeting pathways that mediate this decline have been of high interest, clinically applicable stimulation of β -cell proliferation using biological or pharmacological stimuli has been difficult to achieve^{136,148}. Thus, investigation into the regeneration of β -cells from non- β -cell sources remains highly relevant. Endocrine cell plasticity has been reported through lineage tracing studies in mice whereby non- β -cells, including α -cells or ductal cells, have demonstrated the capacity to transition towards the β -cell lineage^{16,18,19,154,156,157,159,161,230}. Because endocrine cells arise from bipotent endocrine/ductal trunk cells during embryonic development, it has been hypothesized that facultative progenitors reside in the ductal epithelium^{4,6,7}. Thus, a clinically applicable stimulator(s) of this dormant β -cell regenerative remains an elusive target in the search for a curative therapy for diabetes.

The regenerative secretome of bone marrow-derived hMSC represent a promising, readily available biotherapeutic agent to mediate β -cell mass rescue. hMSC can be rapidly expanded *ex vivo*, and the secretome containing regenerative and immunomodulatory stimuli can be concentrated to generate cell-free CM. Although the islet regenerative capacity of hMSC is donor dependent after transplantation and diminishes with prolonged culture^{199,200,207,208}, the activity of the canonical Wnt/ β -catenin signaling pathway has been identified as a key regulator of islet regenerative capacity^{207,208}. Small molecule stimulation of the Wnt pathway using the GSK3 inhibitor CHIR99021 with low-passage hMSC *in vitro* generated CM that reliably rescued glycemia and β -cell mass in hyperglycemic mice. Although increased survival and proliferation of human β -cells was observed^{207,208}, neoislets and insulin+ cell clusters were highly localized adjacent to ductule regions, and glucagon+ cells within islets co-localized with β -cell markers Nkx6.1, MafA, and insulin^{198–200,207}. Thus, harnessing pancreatic plasticity using cell-free hMSC CM represents an attractive approach to modulate β -cell mass. While iPan-injection of Wnt+

hMSC CM reliably rescues hyperglycemia and β -cell mass, the identity of ‘signal-receiving cells’ within the pancreas that mediate islet regeneration remains unknown.

To investigate the identity of the ‘signal-receiving’ cell within the pancreas during hMSC CM induced islet regeneration, we developed a model to focus on CK19-expressing ductal cells. We hypothesized that hMSC CM supplementation *in vitro* would increase proliferation of murine CK19⁺ pancreas cells and stimulate proliferation. Additionally, we hypothesized that CK19-CreERT;Ai9(RCL-tdT) mice would reliably label CK19⁺ cells within the pancreas following tamoxifen administration and become hyperglycemic following STZ treatment. CK19-expressing cells cultured with hMSC CM exhibited increased proliferation *in vitro*. However, neither epithelial-to-mesenchymal transition nor transition towards an endocrine phenotype were observed *in vitro* following hMSC CM supplementation. Additionally, we characterized a lineage tracing mouse model [CK19-CreERT;Ai9(RCL-tdT)] that reliably labelled CK19-expressing cells within the pancreas. This model also exhibited hyperglycemia, impaired glucose tolerance, and reduced β -cell mass following STZ treatment (60 mg/kg/day x 5 days). These data showcase the preparation and optimization of a model that can be confidently used in subsequent experiments to assess the contributions of CK19-expressing cells during hMSC CM induced islet regeneration.

2.2 Methods

2.2.1 Assessing pancreatic phenotypic changes in STZ-treated Non-Obese Diabetic/Severe Combined Immunodeficient (NOD/SCID) mice

Mice (8-10 weeks old) were administered 35 mg/kg/day STZ by intraperitoneal (i.p.) injection for 5 consecutive days. STZ was solubilized in sodium citrate buffer at pH 4.5 and injected into mice within 15 min of preparing the mixture. Mice were monitored for non-fasting blood glucose and body weight at Days 0, 1, 5, and 10. At each timepoint, pancreata were dissected from euthanized mice and digested using collagenase V and trypsin-EDTA. Cells were fixed and permeabilized using 10% formalin and 1% Triton X-100. Single cell suspensions were assessed for DBA lectin (Vector Laboratories, Burlington, ON) uptake, CK19 (Abcam, Cambridge, UK), CD45 (BioLegend, San Diego, CA), and F4/80 (BioLegend) expression by flow cytometry on an LSRII flow cytometry machine (BD Biosciences, Mississauga, ON). Flow cytometry data were analyzed using FlowJo software (Treestar, Ashland, OR, USA).

2.2.2 Validating the effects of CHIR99021 and IWR-1 on intracellular β -catenin in hMSC

Human bone marrow was obtained with informed consent from healthy donors at the London Health Sciences Centre (London, ON, Canada). hMSC were purified using density gradient centrifugation and cultured in supplemented AmniomaxTM media (Invitrogen, Carlsbad, CA) for expansion^{199,200}. Low passage (P3-P4), 80% confluent hMSC cultures were washed with phosphate-buffered saline (PBS) to remove serum and growth factors, then cultured in serum-free basal AmniomaxTM media supplemented with increasing concentrations of CHIR99021 (0 μ M, 5 μ M, 10 μ M, 15 μ M, 20 μ M; AbMole Bioscience, Houston, TX) or IWR-1 (0 μ M, 10 μ M, 20 μ M, 30 μ M, 50 μ M, Sigma-Aldrich, St. Louis, MO). In cell cultures without CHIR99021 or IWR-1, dimethyl sulfoxide (DMSO) was added as a vehicle control. Cells were fixed in 10% formalin and permeabilized using 1% Triton X-100. hMSC were assessed for survival [(7-Aminoactinomycin D, 7-AAD (BioLegend)], apoptosis [(Annexin V (BD Biosciences)], and β -catenin (Invitrogen) expression by flow cytometry at the London Regional Flow Cytometry Facility and analyses were performed using Flowjo software.

2.2.3 Generating hMSC CM

Low passage (P4), 80% confluent hMSC were washed with PBS to remove serum and growth factors and cultured in serum-free basal AmniomaxTM media supplemented with either DMSO (vehicle control), 10 μ M CHIR99021, or 20 μ M IWR-1 for 24h to generate Untreated, Wnt+, and Wnt- CM, respectively. CM was collected and concentrated (\approx 40-fold) by centrifugation at 4,100 g for 75 minutes using 3 kDa filter spin columns. Secreted contents $>$ 3 kDa separated by the filter were collected and the CM protein concentration was quantified using a NanoDrop analyzer.

2.2.4 Murine ductal cell culture and hMSC CM supplementation

Pancreata from healthy or STZ-treated adult mice (8-10 weeks old) were purified using fluorescence activated cell sorting (FACS) at the London Regional Flow Cytometry Facility (London, ON) to obtain 7AAD-/Dolichos Biflorus Agglutinin (DBA) lectin+ cells following collagenase V and trypsin EDTA-mediated tissue digestion according to the protocol previously outlined by Reichart *et al*²³¹ (**Fig. 2.1**). 7-AAD marks dead cells with compromised membrane integrity by intercalating double-stranded DNA²³². DBA lectin has carbohydrate specificity toward α -linked N-acetylgalactosamine common on ductal epithelial cells²³³. DBA lectin+ cell cultures were first established in complete pancreatic ductal cell (PDC) media [Dulbecco's Modified Eagle Medium/Ham's F-12 (DMEM/F-12) + 5% Nu Serum, 25 μ g/ml bovine pituitary extract, 0.5% ITS+ (insulin, human transferrin, selenous acid) Premix, 20 ng/ml epidermal growth factor, 1 μ M dexamethasone, 5 mg/ml glucose, 1.22 mg/ml nicotinamide] for 24 hours before replacing media with either complete PDC media, basal DMEM/F-12, or DMEM/F-12 supplemented with Untreated, Wnt+, or Wnt- hMSC CM (protein dose of 8 μ g/ well for approximately 8,000 cells) for 2 or 5 days at 37°C + 5% CO₂. Cell cultures were assessed for proliferative response using ethynyldeoxyuridine (EdU) incorporation following 24h pulse label at 50 μ M, and phenotype transition (vimentin, insulin, glucagon expression) was assessed by immunofluorescence. Ductal cell phenotype was verified using CK19 labeling.

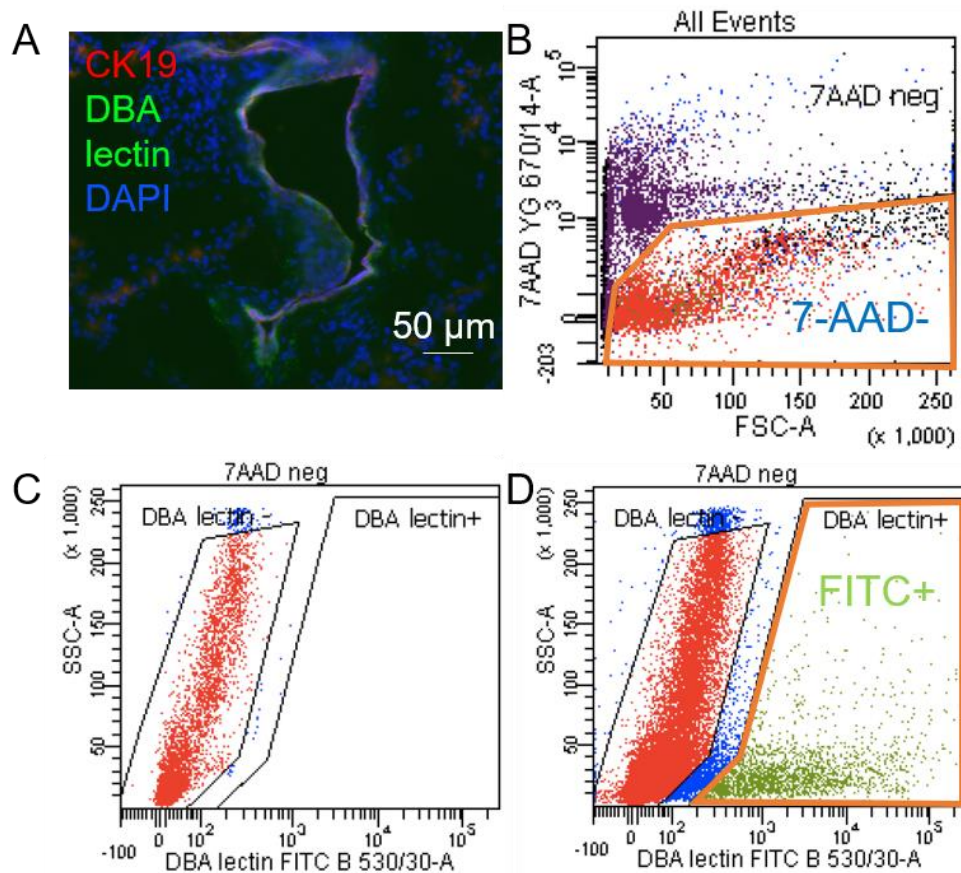

Figure 2.1 Fluorescence-activated cell sorting (FACS) strategy to isolate murine 7-AAD-/DBA lectin+ cells. (A) Representative photomicrograph of a mouse pancreas section for DBA lectin showed cellular co-localization with CK19. Pancreata from mice (8-10 weeks old) were digested and single cell suspension was purified by FACS with a strategy for (B) live (7-AAD-) cells, (C) setting a gate for DBA lectin using unstained samples, and (D) sorting for DBA lectin+ cells.

2.2.5 Optimization of STZ treatment in CK19-CreERT;Ai9(RCL-tdT) mice

CK19-CreERT;Ai9(RCL-tdT) mice (8-12 weeks old) [breeding CK19-CreERT mice (Jackson Labs, Bar Harbor, Maine, USA) with Ai9(RCL-tdT) mice (Jackson Labs, Bar Harbor, Maine, USA)] were treated with increasing concentrations of STZ (40 mg/kg/day, 50 mg/kg/day, 60 mg/kg/day, or 65 mg/kg/day) dissolved in citric acid buffer (CAB) for 5 consecutive days by i.p. injection and assessed for non-fasting blood glucose and body weight at Days 0, 7, 10, and 14.

2.2.6 Islet size, number, and β -cell mass quantification

Pancreata from STZ-treated CK19-CreERT;Ai9(RCL-tdT) mice sacrificed at Day 14 were frozen in optimal cutting temperature media and sectioned (12 μ m) so each of the 3 sections per slide were >150 μ m apart. Sections were fixed in formalin, blocked with peroxidase block and horse serum, and stained for insulin using a mouse insulin primary antibody (Sigma) and detected using a peroxidase anti-mouse secondary antibody (Vector Laboratories). *ImmPACT*[™] DAB (Vector Laboratories) staining was performed to detect antibody binding, followed by hematoxylin counterstain and mounting in Vectamount (Vector Laboratories). A minimum of 10 clustered insulin+ cells was required to be classified as an islet. Islet number and size were quantified using light microscopy and ImageScope x64 software, counting all islets within 3 sections per mouse. β -cell mass was calculated by:

$$\beta \text{ cell mass} = \frac{\beta \text{ cell area}}{\text{Total pancreas section area}} \times \text{Pancreas weight}$$

2.2.7 Glucose tolerance test

CK19-CreERT;Ai9(RCL-tdT) mice treated with 60 mg/kg/day of STZ (Days 1-5) and CAB control mice were fasted for 3 hours on Day 14 before receiving bolus glucose (2 mg/kg) by i.p. injection. Blood glucose was assessed at 0, 5, 10, 15, 30, 45, 60, 90, and 120 minutes.

2.2.8 Assessing pancreatic phenotypic changes in STZ-treated CK19-CreERT;Ai9(RCL-tdT) mice

Mice (8-10 weeks old) were administered 6 mg tamoxifen dissolved in corn oil by oral gavage. After 7 days of rest, mice were treated with 60 mg/kg/day STZ by i.p. injection for 5 consecutive days. Mice were monitored for non-fasting blood glucose and body weight at Days 0, 1, 7, and 14. At each timepoint, pancreata were dissected and digested using collagenase V and TrypLE (Thermo Fisher). Cells were fixed and permeabilized using 10% formalin and 1% Triton X-100. Single cell suspensions were assessed for tdTomato, CK19 (Abcam), insulin (BD Biosciences), and CD45 (BioLegend) expression by flow cytometry. Data were analyzed using FlowJo software.

2.2.8 Statistical Analysis

All data was expressed as mean \pm standard deviation (SD) unless otherwise stated. Analysis was performed by a two-way analysis of variance (ANOVA) for blood glucose curves, and by one-way ANOVA followed by Tukey's multiple comparison test for all other analyses, unless otherwise stated.

2.3 Results

2.3.1 STZ treatment induced systemic hyperglycemia and increased the frequency of DBA lectin+ cells within the pancreas

To investigate the effects of STZ on mouse CK19, CD45 (pan-leukocyte marker), DBA lectin (binds to the α -linked N-acetylgalactosamine carbohydrate moiety), and F4/80 (mouse macrophage marker) expression, NOD/SCID mice were injected with 35 mg/kg/day of STZ for 5 consecutive days and mouse pancreata were harvested and assessed for the frequency of CD45+, CK19+, and DBA lectin+ expression at Days 0, 1, 5, and 10 (Figure 2.2D-I). Mice demonstrated increased non-fasting blood glucose levels at Day 10 compared to Days 0, 1, and 5 (Figure 2.2A). Additionally, the proportion of insulin+ cells was significantly decreased at Days 1 and 10, while the proportion of glucagon+ cells did not change across time (Figure 2B,C). While the proportion of CD45+ and CK19+ within the pancreas did not change over time, the proportion of DBA lectin+ cells was significantly increased at Day 10 compared to Day 0 (Figure 2.2J and K). While CK19 expression is commonly used as a pancreatic ductal marker, it requires cell fixation and permeabilization for detection²³⁴. However, to purify viable ductal cells for subsequent culture, identification of a live cell marker was required. Various studies have cited DBA lectin as a ductal epithelial marker within the pancreas^{231,233,235-240}. However, DBA lectin can also bind non-specifically to some hematopoietic cells including macrophages²⁴¹⁻²⁴⁴. Within the DBA lectin+ cell population, the proportion of CK19+ cells was enriched two-fold compared to ungated cells ($\approx 40\%$ vs. $\approx 20\%$, respectively)(Figure 2.2 H). In contrast, the proportion of CD45+ cells within DBA lectin+ cells did not change compared to ungated cells. Although the DBA lectin+ cell population was comprised of 20% hematopoietic cells, isolation of live DBA lectin+ cells by FACS followed by 24-hour culture in complete PDC media resulted in 83% CK19+ cell purity (CK19+/DAPI+ cells). Therefore, isolation of pancreatic DBA lectin+ cells followed by culture in complete PDC media represents a purification strategy for murine CK19+ ductal epithelial cells.

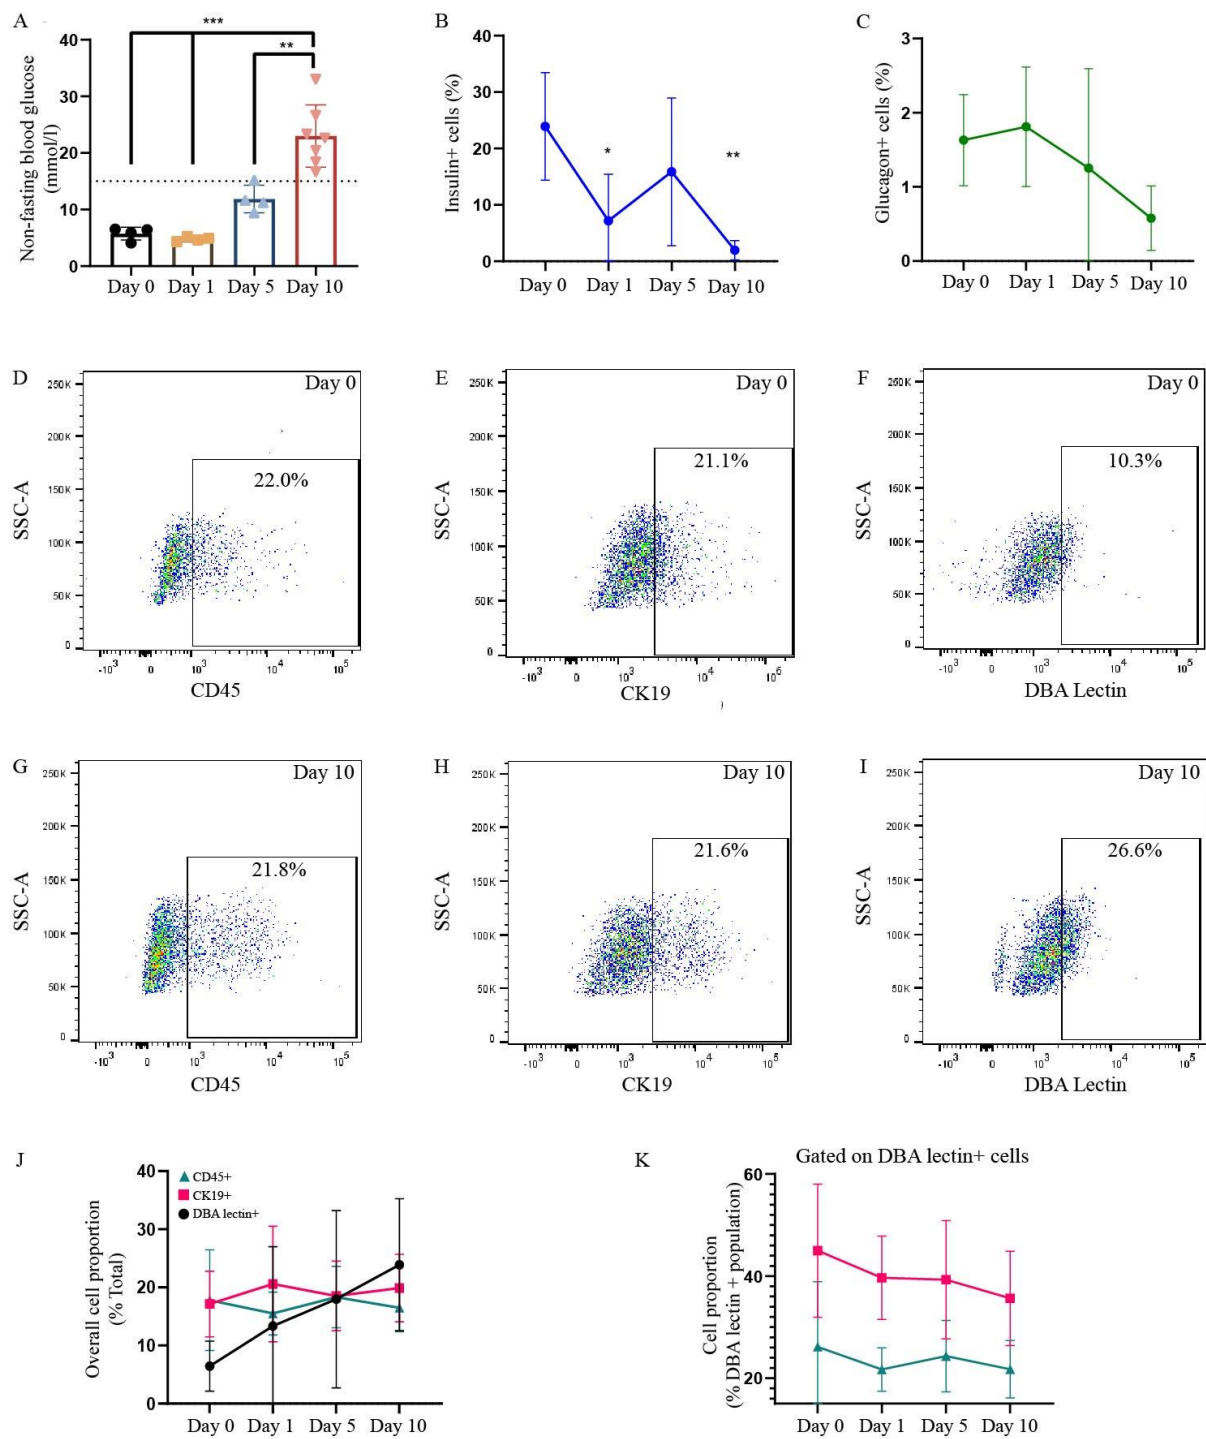

Figure 2.2 STZ treatment induced systemic hyperglycemia and increased the proportion of DBA lectin+ cells within the pancreas. NOD/SCID mice (8-10 weeks old) were treated with 35 mg/kg/day STZ for 5 days (Days 1-5). At Day 0 (n=3-4), Day 1 (n=4), Day 5 (n=4), and Day 10 (n=7) mouse pancreata were assessed for insulin+, glucagon+, DBA lectin+, CK19+, and CD45+ cell frequencies by flow cytometry. **(A)** At Day 10 mice demonstrated significantly increased non-fasting blood glucose levels compared to all other timepoints. **(B)** The proportion of insulin+ β -cells was significantly decreased at Days 1 and 10 compared to Day 0. **(C)** The proportion of glucagon+ α -cells did not change across time. Representative plots for DBA lectin+, CK19+, and CD45+ cells are shown at **(D-F)** Day 0 and **(G-I)** Day 10. **(J)** The proportion of DBA lectin+ cells was significantly increased at Day 10 compared to Day 0 (* $p < 0.05$). The proportions of CK19+ and CD45+ cells showed no change with time. **(I)** Within the DBA lectin+ cell population, the proportion of CK19+ cells was enriched two-fold compared to ungated cells. In contrast, the proportion of CD45+ cells within DBA lectin+ cells did not change compared to ungated cells. Data represent mean \pm SD compared using a one-way ANOVA followed by Tukey's multiple comparison test. (** $p < 0.01$, *** $p < 0.001$)

2.3.2 STZ treatment increased the proportion of F4/80+ cells within CD45+ and CK19+ cells within the pancreas

To assess potential macrophage infiltration in response to STZ treatment, mouse pancreata were assessed for F4/80+ expression, a widely used mouse macrophage marker²⁴⁵⁻²⁴⁷ (Figure 2.3 A-D). At Day 10, increased hematopoietic macrophage infiltration was observed, as there was an increase in the proportion of F4/80+ cells within the pancreas and within the CD45+ cell compartment compared to Day 0 (Figure 2.3E,F). Within the CK19+ cell population, the proportion of F4/80+ cells was increased at Day 5 compared to Day 1 (Figure 2.3G). Within DBA lectin+ cells, the proportion of F4/80+ cells remained unchanged with time (Figure 2.3H). Collectively, these data suggest that macrophage infiltration was observed following STZ treatment, which may play a role in islet destruction.

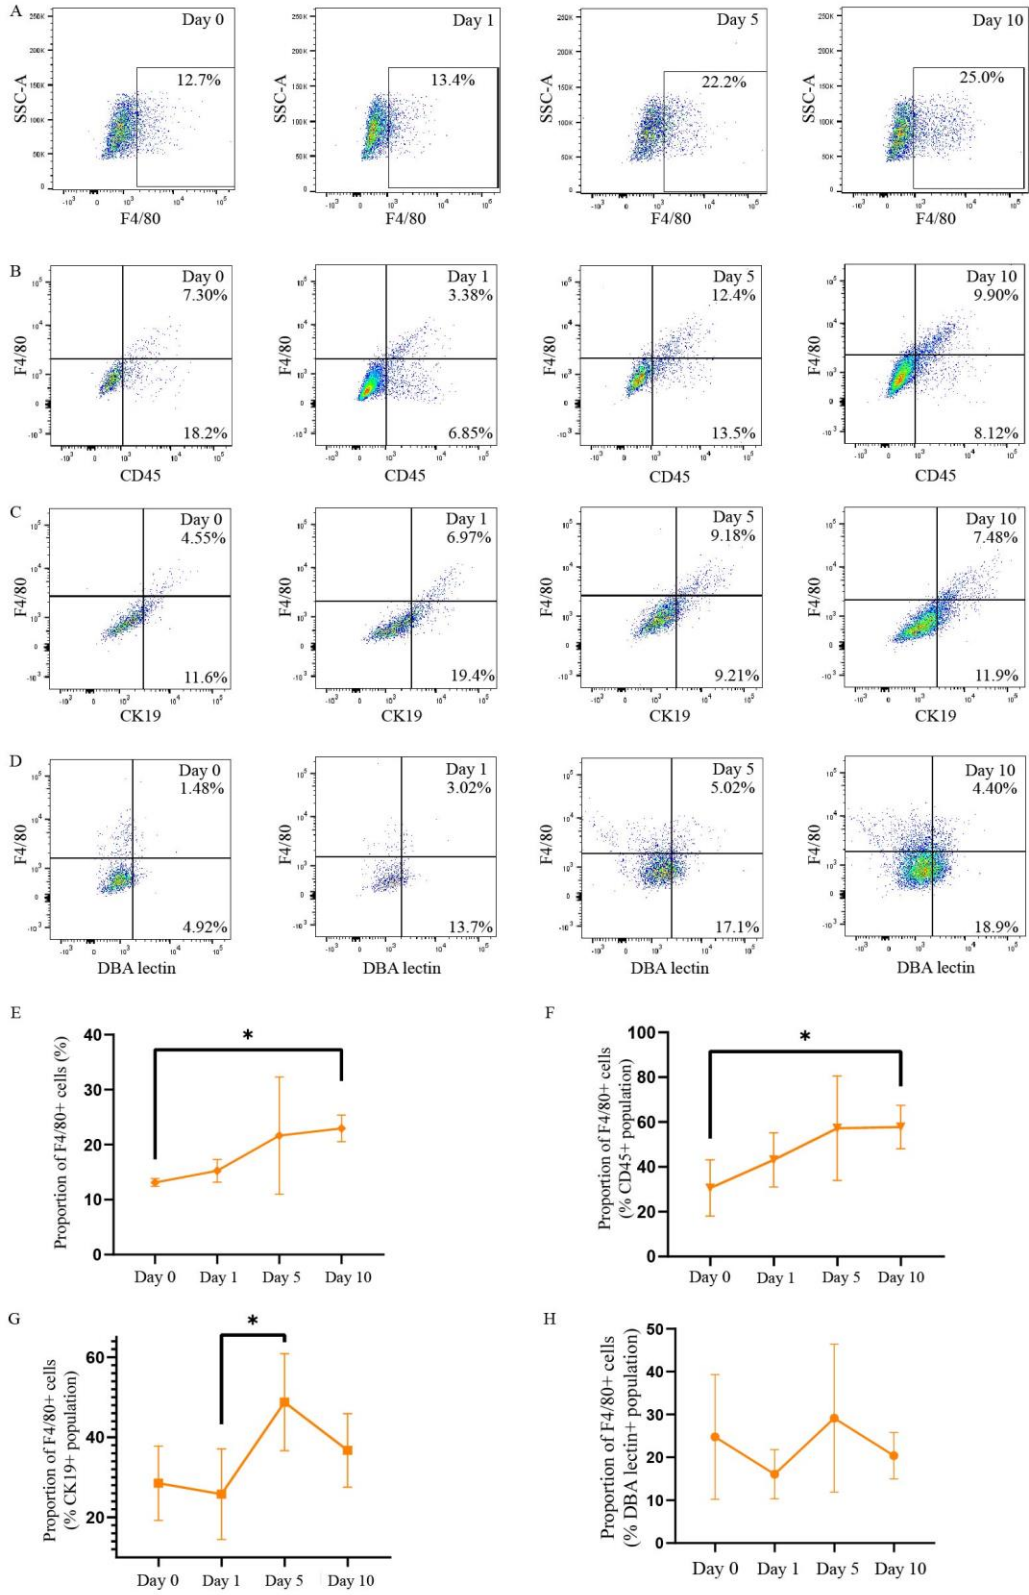

Figure 2.3 STZ treatment increased the proportion of F4/80+ macrophages within CD45+ and CK19+ cell populations within the pancreas. NOD/SCID mice (8-10 weeks old) were treated with 35 mg/kg/day STZ for 5 days (Days 1-5). At Day 0 (n=3-4), Day 1 (n=4), Day 5 (n=4), and Day 10 (n=7), mouse pancreata were assessed for DBA lectin+, CK19+, CD45+, and F4/80+ cell frequencies by flow cytometry. **(A)** Representative dot plots showing the overall proportion of F4/80+ macrophages in the pancreas at each timepoint are shown. **(B)** Representative dot plots showing the proportion of F4/80+ cells within CD45+ leukocytes at each timepoint are shown. **(C)** Representative dot plots showing the proportion of F4/80+ macrophages within CK19+ ductal cells at each timepoint. **(D)** Representative dot plots showing the proportion of F4/80+ cells within DBA lectin+ cells at each timepoint. **(E)** The proportion of F4/80+ macrophages in the pancreas was significantly increased at Day 10 compared to Day 0. **(F)** The proportion of F4/80+ macrophages within CD45+ leukocytes was significantly increased at Day 10 compared to Day 0. **(G)** The proportion of F4/80+ macrophages within the CK19+ ductal cell population was significantly increased at Day 5 compared to Day 1. **(H)** The proportion of F4/80+ macrophages remained unchanged within the DBA lectin+ cell population over the 10-day time course. Data represent mean \pm SD compared using a one-way ANOVA followed by Tukey's multiple comparison test (* $p < 0.05$).

2.3.3 Treatment of hMSC with CHIR99021 increased intracellular β -catenin and did not affect cell survival

As the GSK3 inhibitor CHIR99021 promotes destabilization of the β -catenin destruction complex, increasing intracellular stores of β -catenin which affects transcription of factors implicated in cell growth, proliferation, and differentiation²⁰⁸. Therefore, we sought to titrate CHIR99021 treatment concentration to optimally stimulate the Wnt pathway in cultured hMSC, measured by intracellular β -catenin levels^{208,248,249}. Following 24-hour treatment, hMSC treated with 10 μ M, 15 μ M, or 20 μ M CHIR99021 in serum-free basal AmniomaxTM media showed significantly increased mean fluorescence intensity (M.F.I.) of intracellular β -catenin by flow cytometry compared to the DMSO control (0 μ M) and 5 μ M treatment (** $p < 0.001$)(Figure 2.4). Treatment with 5 μ M showed no difference in β -catenin M.F.I. compared to the DMSO control. There were no significant differences in the frequency of dead cells (7AAD+/Annexin V+) or apoptotic cells (7AAD-/Annexin V+) between any of the treatment conditions (Figure 2.5). Thus, 10 μ M CHIR99021 was chosen to optimally stimulate the canonical Wnt/ β -catenin pathway in hMSC.

2.3.4 Treatment of hMSC with IWR-1 did not affect intracellular β -catenin or cell survival

In contrast, IWR-1 stabilizes Axin, and by extension promotes the intracellular destruction of β -catenin resulting in the blockade of canonical Wnt/ β -catenin signaling. Next, we sought to titrate the optimal IWR-1 treatment concentration to inhibit the Wnt-pathway in cultured hMSC, as measured by intracellular β -catenin levels^{208,214,249}. Following 24-hour treatment, hMSC treated with 10 μ M, 20 μ M, 30 μ M, or 50 μ M IWR-1 in basal AmniomaxTM media surprisingly showed no significant difference in intracellular β -catenin M.F.I. by flow cytometry compared to the DMSO control (0 μ M) (Figure 2.6). In addition, here were also no significant differences in the frequency of dead cells (7AAD+/Annexin V+) or apoptotic cells (7AAD-/Annexin V+) between the treatment conditions (Figure 2.7). These results contradict previous findings which identified 20 μ M IWR-1 treatment to optimally inhibit the Wnt/ β -catenin pathway^{207,208}.

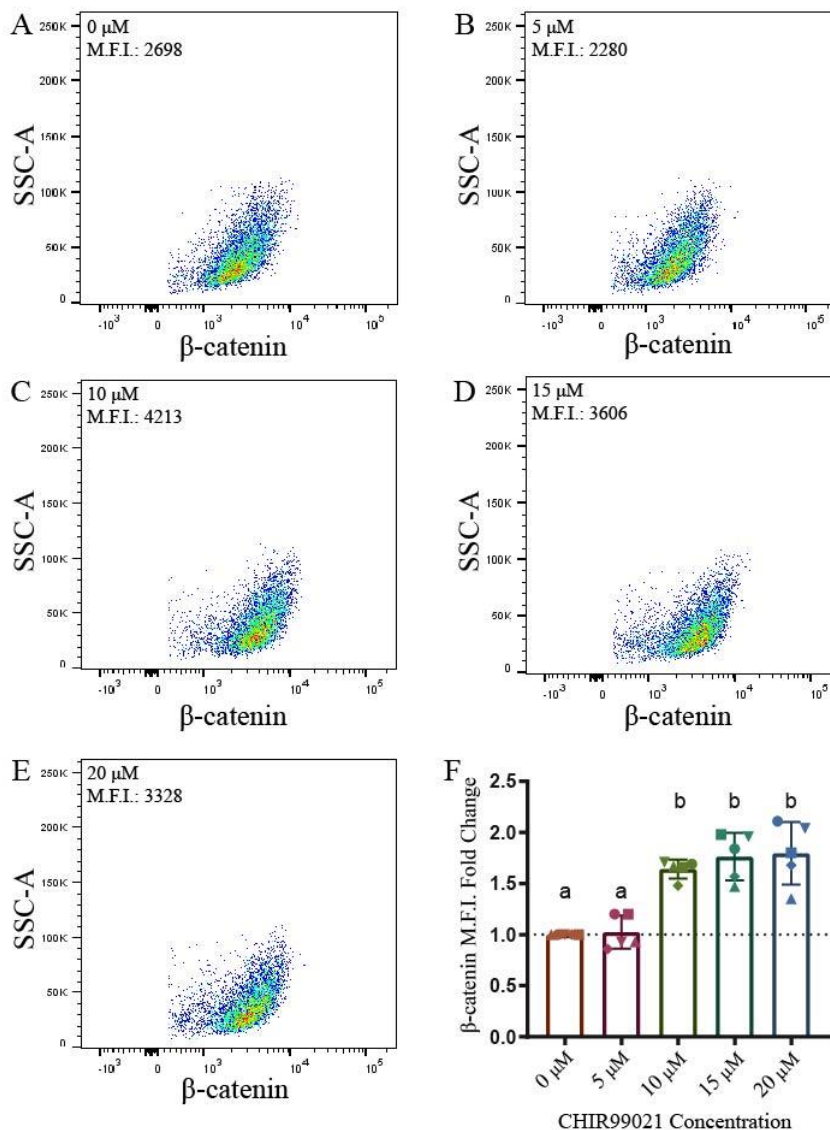

Figure 2.4 Treatment of hMSC with CHIR99021 increased intracellular β-catenin. Low passage (P3-P4), 80% confluent hMSC (N=5) were treated with 5 μM, 10 μM, 15 μM, or 20 μM of CHIR99021 or DMSO (0 μM) for 24 hours in basal Amniomax™ media and assessed for intracellular β-catenin M.F.I. by flow cytometry. (A-E) Representative β-catenin vs. SSC-A dot plots for 0 μM, 5 μM, 10 μM, 15 μM, and 20 μM treatments with CHIR99021 are shown. (F) Treatment with 10 μM, 15 μM, and 20 μM of CHIR99021 significantly increased β-catenin M.F.I. compared to the DMSO control (***p<0.001). Data represent mean fold change ± SD compared using a one-way ANOVA followed by Tukey's multiple comparison test. Means with different letters represent significantly different values.

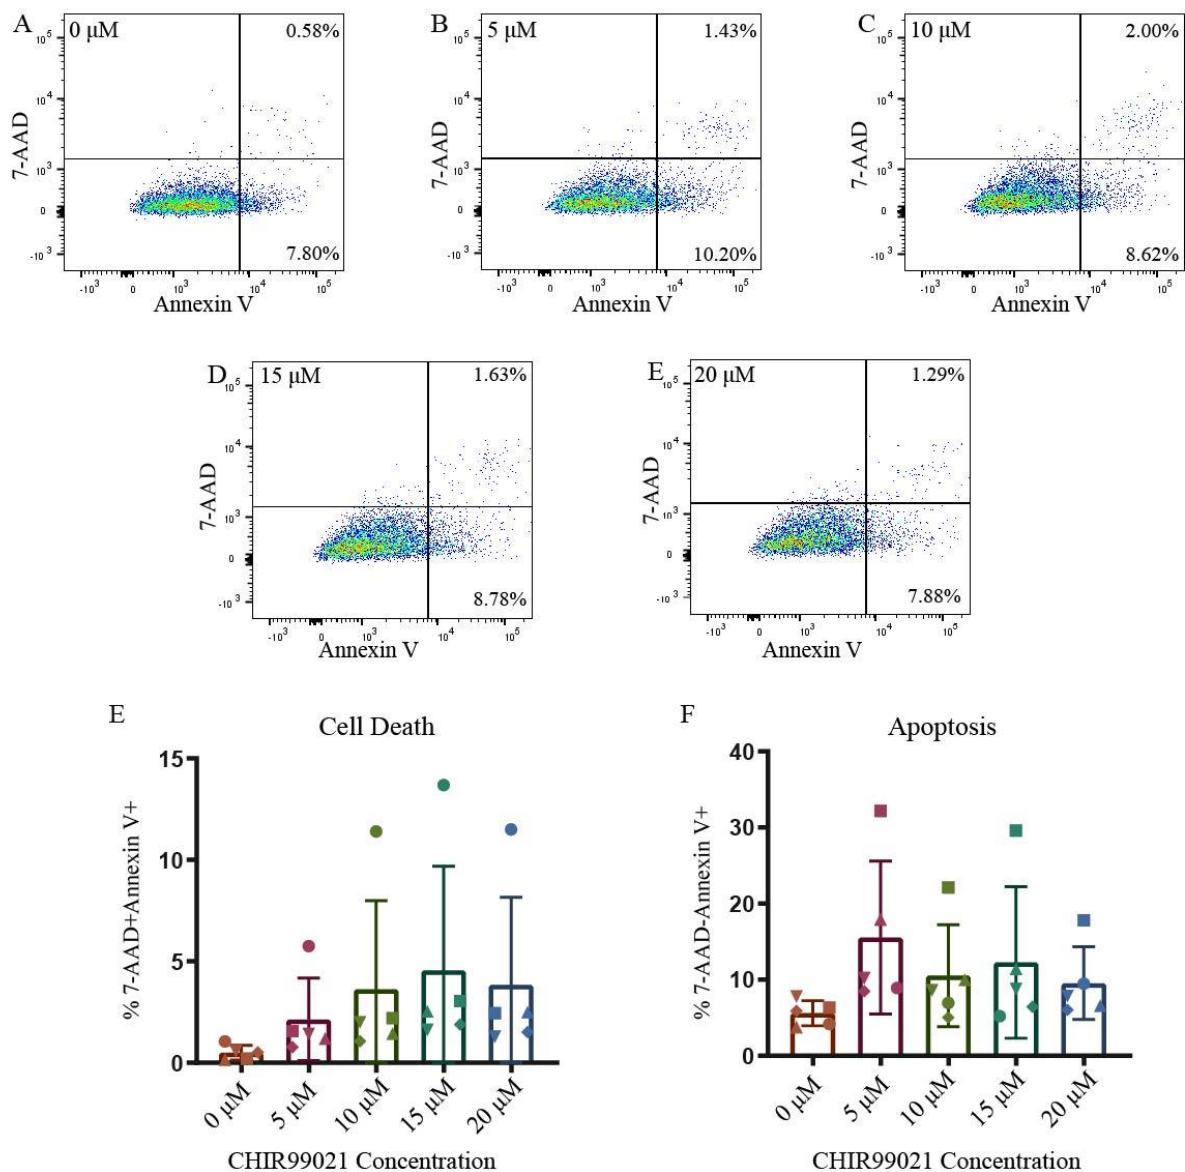

Figure 2.5 Treatment with CHIR99021 did not affect hMSC survival or apoptosis. Low passage (P3-P4), 80% confluent hMSC (N=5) were treated with 5 μM, 10 μM, 15 μM, or 20 μM of CHIR99021 or DMSO (0 μM) for 24 hours in basal Amniomax™ media and assessed for cell death (7-AAD⁺) and apoptosis (Annexin V⁺) by flow cytometry. (A-E) Representative dot plots for 7-AAD and Annexin V for 0 μM, 5 μM, 10 μM, 15 μM, and 20 μM treatment with CHIR99021 are shown. Treatment with CHIR99021 did not alter (F) cell death (proportion of 7-AAD⁺/Annexin V⁺ cells) or (G) apoptosis (7-AAD⁻/Annexin V⁺ cells). Data represents mean ± SD compared using a one-way ANOVA.

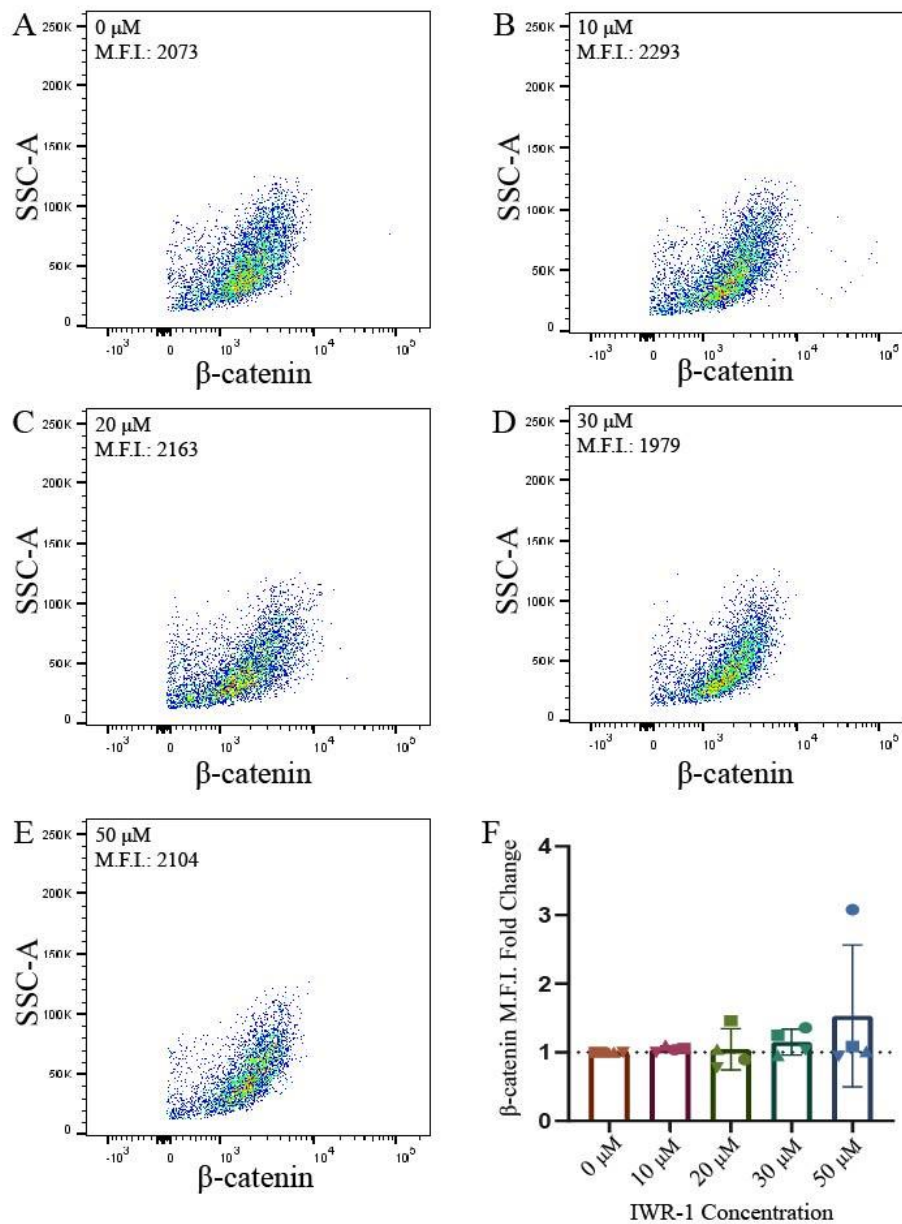

Figure 2.6 Treatment of hMSC with IWR-1 did not affect intracellular β -catenin levels.

Low passage (P3-P4), 80% confluent hMSC (N=4) were treated with 10 μ M, 20 μ M, 30 μ M, or 50 μ M of IWR-1 or DMSO (0 μ M) for 24 hours in basal Amniomax™ media and assessed for intracellular β -catenin M.F.I. by flow cytometry. (A-E) Representative β -catenin vs. SSC-A dot plots for 0 μ M, 10 μ M, 20 μ M, 30 μ M, and 50 μ M IWR-1 are shown. (F) Treatment with IWR-1 did not alter β -catenin M.F.I. compared to DMSO (0 μ M) control. Data represent mean fold change \pm SD compared using a one-way ANOVA.

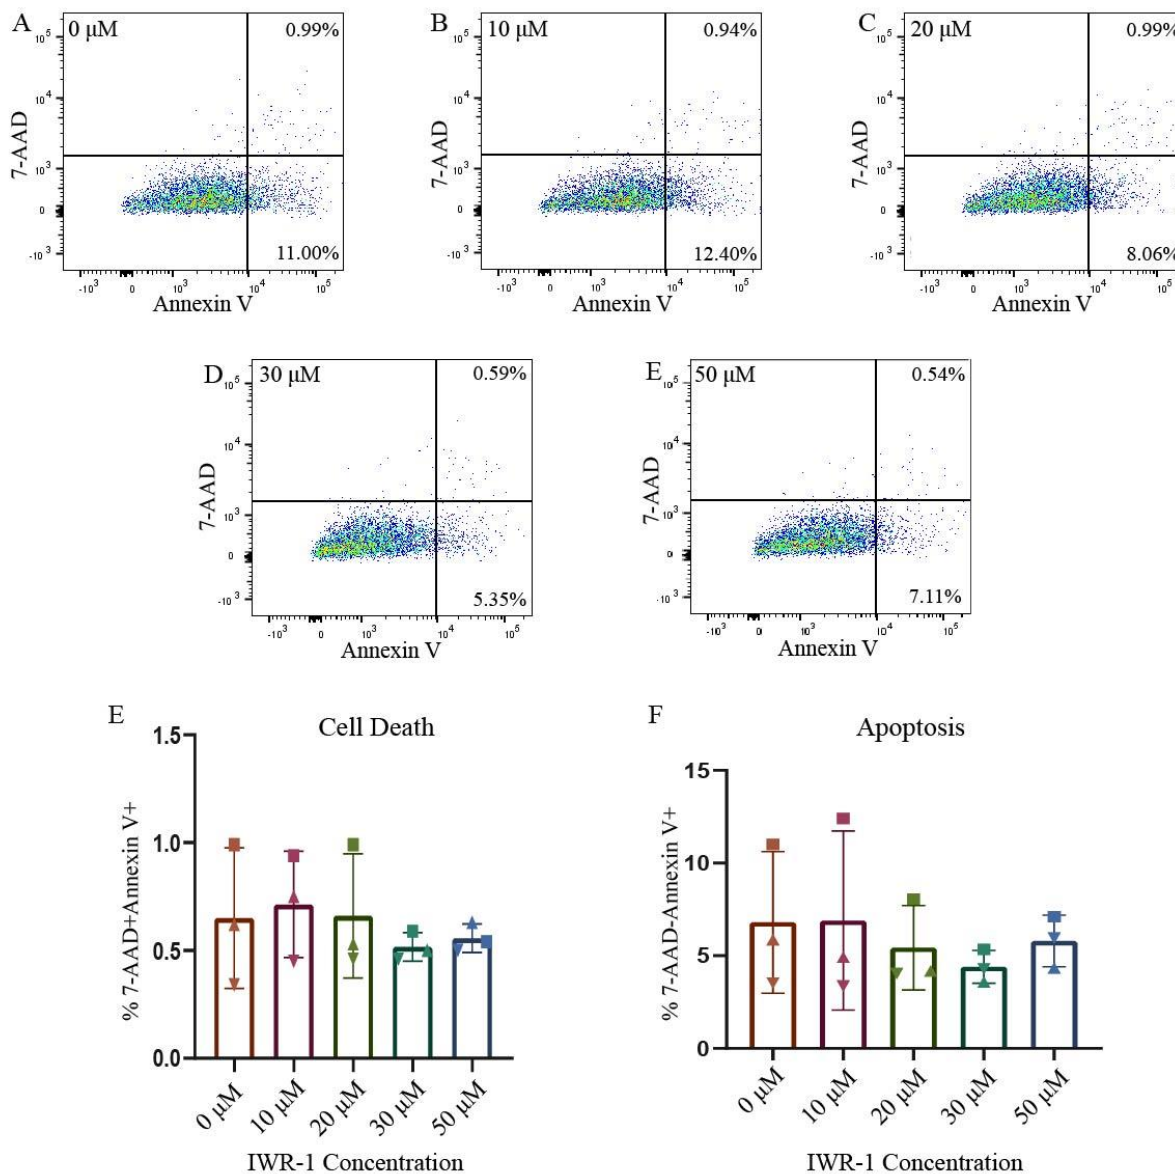

Figure 2.7 Treatment with IWR-1 did not affect hMSC survival or apoptosis. Low passage (P3-P4), 80% confluent hMSC (N=3) were treated with 10 μ M, 20 μ M, 30 μ M, or 50 μ M of IWR-1 or DMSO for 24 hours in basal AmniomaxTM media and assessed for cell death (7-AAD+) and apoptosis (Annexin V+) by flow cytometry. (A-E) Representative dot plots for 7-AAD and Annexin V are shown for 0 μ M, 10 μ M, 20 μ M, 30 μ M, and 50 μ M IWR-1. Treatment with IWR-1 did not alter the proportion of (F) dead cells (7-AAD+/Annexin V+) or (G) apoptotic cells (7-AAD-/Annexin V+) compared to DMSO (0 μ M). Data represents mean \pm SD compared using a one-way ANOVA.

2.3.5 hMSC CM stimulated proliferation of CK19+ cells *in vitro*

To investigate the effects of hMSC CM supplementation on cultured CK19-expressing cells, FACS isolated 7-AAD-/DBA lectin+ cells from healthy or STZ-treated (35 mg/kg/day) NOD/SCID mice (8-10 weeks old) were cultured in complete PDC media for 24 hours to facilitate cell adhesion. Cell media was then replaced either with complete PDC media, basal DMEM/F-12, or DMEM/F-12 supplemented with Untreated, Wnt+, or Wnt- hMSC CM. After 2 or 5 days, CK19+ cells were assessed for proliferation (24-hour EdU pulse label). After 2 days in culture, DBA lectin+ cells isolated from healthy mice supplemented with Untreated, Wnt+, or Wnt- CM showed significantly increased frequencies of proliferating CK19+ cells compared to basal DMEM/F-12 (Figure 2.8F). Ductal cell cultures with bovine serum albumin (BSA) showed no significant change in proliferation frequency, indicating that hMSC CM benefits were not a result of generic protein supplementation in culture. After 5 days culture, there was no significant difference in the frequencies of proliferating CK19+ cells between hMSC CM supplemented and basal DMEM/F-12 conditions. DBA lectin+ cells isolated from STZ-treated mice showed no difference in the frequency of proliferating CK19+ cells after 2 or 5 days in culture (Figure 2.8G). Additionally, DBA lectin+ cells purified from STZ-treated mice exhibited decreased frequencies of EdU+/CK19+ cells compared to cells isolated from healthy mice after 2 days culture (Figure 2.9).

2.3.6 Epithelial-to-mesenchymal transition and endocrine phenotype acquisition were not observed in DBA lectin+ cells exposed to hMSC CM *in vitro*

While hMSC CM supplementation increased CK19-expressing cell proliferation *in vitro*, the next point of interest was whether hMSC CM affected cell phenotype and differentiation. FACS purified 7AAD-/DBA lectin+ cells from healthy or STZ-treated mice cultured in complete PDC media, basal DMEM/F-12, or DMEM/F-12 supplemented with Untreated, Wnt+, or Wnt- hMSC CM for 2, 4, or 7 days did not show colocalization of vimentin and CK19, suggesting no EMT was observed *in vitro*. Similarly, endocrine phenotype transition was not observed, as colocalization of glucagon or insulin with CK19 was not identified at each of these timepoints (Figure 2.10). Thus, mesenchymal or endocrine phenotype transition were not observed under these culture conditions, future studies can look at earlier markers of mesenchymal or endocrine phenotype, including mRNA or transcription factor changes.

Figure 2.8 Treatment with hMSC CM increased the frequency of proliferating CK19+ cells *in vitro*. FACS isolated 7-AAD-/DBA lectin + cells from healthy or STZ-treated 8-10 week-old mice were cultured in (A) complete PDC media, (B) basal DMEM/F-12, or DMEM/F-12 supplemented with (C) Untreated, (D) Wnt+, or (E) Wnt- hMSC CM (N=4). After 2 or 5 days, CK19+ cells were assessed for proliferation [EdU incorporation following 24h pulse label (50 μ M)]. Arrows indicate DAPI+/CK19+/EdU+ cells. (F) DBA lectin+ cells from healthy mice cultured in DMEM/F-12 supplemented with Untreated, Wnt+, or Wnt- hMSC CM showed significantly increased frequencies of EdU+/CK19+ cells after 2 days of culture compared to DBA lectin+ cells cultured in basal DMEM/F-12. After 5 days culture, there was no significant difference in the frequency of EdU+/CK19+ cells between CM supplemented cultures and culture in basal DMEM/F-12. (G) DBA lectin+ cells isolated from STZ-treated mice showed no significant difference in the frequency of proliferating CK19+ cells after 2 or 5 days in culture. Data represent mean \pm SD compared using a one-way ANOVA followed by Tukey's multiple comparison test comparing back to DMEM/F-12 for each timepoint (* p <0.05, ** p <0.01).

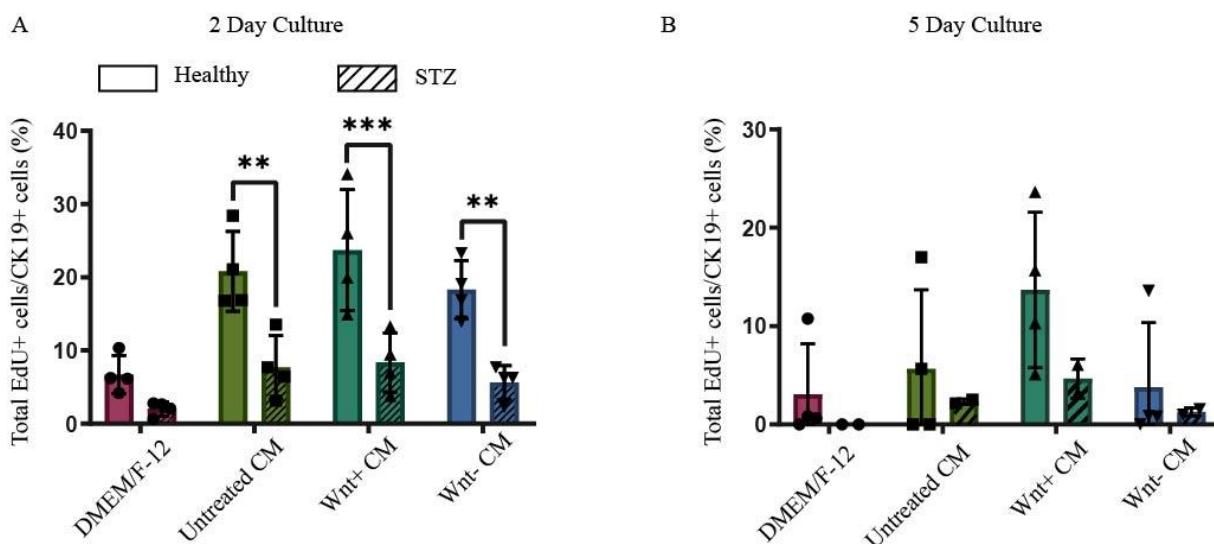

Figure 2.9 STZ treatment decreased DBA lectin+ pancreatic cell proliferation *in vitro*. FACS purified 7-AAD-/DBA lectin+ pancreatic cells from 8-10 week-old healthy or STZ-treated mice were cultured in complete PDC media, basal DMEM/F-12 media, or DMEM/F-12 supplemented with Untreated, Wnt+, or Wnt- hMSC CM for 2 or 5 days. DBA lectin+ cells purified from STZ-treated mice exhibited decreased frequencies of EdU+/CK19+ cells compared to cells isolated from healthy mice at (A) 2 days or (B) 5 days of culture (N=2-4). Data represent mean \pm SD compared using a two-way ANOVA followed by Tukey's multiple comparison test (** $p < 0.01$, *** $p < 0.001$).

Figure 2.10 Epithelial-to-mesenchymal transition and endocrine phenotype acquisition were not observed in DBA lectin+ cells exposed to hMSC CM *in vitro*. FACS purified 7-AAD-/DBA lectin+ cells from healthy or STZ-treated mice were cultured in complete PDC media, basal DMEM/F-12 media, or DMEM/F-12 supplemented with Untreated, Wnt+, or Wnt- hMSC CM in DMEM/F-12 for 2, 4, or 7 days. Representative photomicrographs of (A) mouse islets and (B) DBA lectin+ cells (cultured in DMEM/F-12 supplemented with Wnt+ CM) stained for vimentin and CK19. No co-localization of vimentin and CK19 was observed. Representative photomicrographs of (C) a mouse pancreas section and (D) DBA lectin+ cells (cultured in DMEM/F-12 supplemented with Wnt+ hMSC CM) showed no co-localization of glucagon or insulin (not shown) with CK19.

2.3.7 STZ Treatment (60 mg/kg/day x 5 days) induced hyperglycemia in CK19-CreERT;Ai9(RCL-tdT) mice

To assess the optimal STZ dose to induce hyperglycemia and reduce β -cell mass, CK19-CreERT;Ai9(RCL-tdT) mice (8-12 weeks old) were treated with 40, 50, 60, or 65 mg/kg/day STZ for 5 consecutive days (Days 1-5). On Days 0, 7, 10 and 14, mice were assessed for non-fasting blood glucose and body weight. Treatment with 60 mg/kg/day of STZ resulted in significantly increased non-fasting blood glucose levels at Day 14 compared to Day 0 and Day 7 (Figure 2.11A). Treatment with 40, 50, or 65 mg/kg/day showed no differences in non-fasting blood glucoses over time. There were no significant differences in the area under the curve (A.U.C.) for blood glucose between Days 0 and 14 for STZ-treated mice compared to CAB control mice (Figure 2.11B). Assessing differences between the effects of STZ administration in males vs. females on blood glucose, male mice administered 60 mg/kg/day exhibited significantly increased non-fasting blood glucose levels at Day 14 compared to Day 7 (Figure 2.11C). No differences over time were observed in other male/female groups administered STZ. There were no significant differences in A.U.C. for blood glucose between males/females administered STZ compared to CAB control mice (Figure 2.11D). Mice treated with 50, 60, or 65 mg/kg/day of STZ demonstrated weight loss (D14/D0) compared to CAB control mice, which should be monitored upon further experimentation and extension of the model (Figure 2.11E). Among STZ-treated mice, those administered 60 mg/kg/day produced the highest proportion (30%) of mice with non-fasting blood glucose levels ≥ 15 mmol/l at Day 14 (Figure 2.11F). Mice deemed hyperglycemic and suitable for hMSC CM transplantation should have non-fasting blood glucose between 15 and 25 mmol/l^{199,200,207,225,226}.

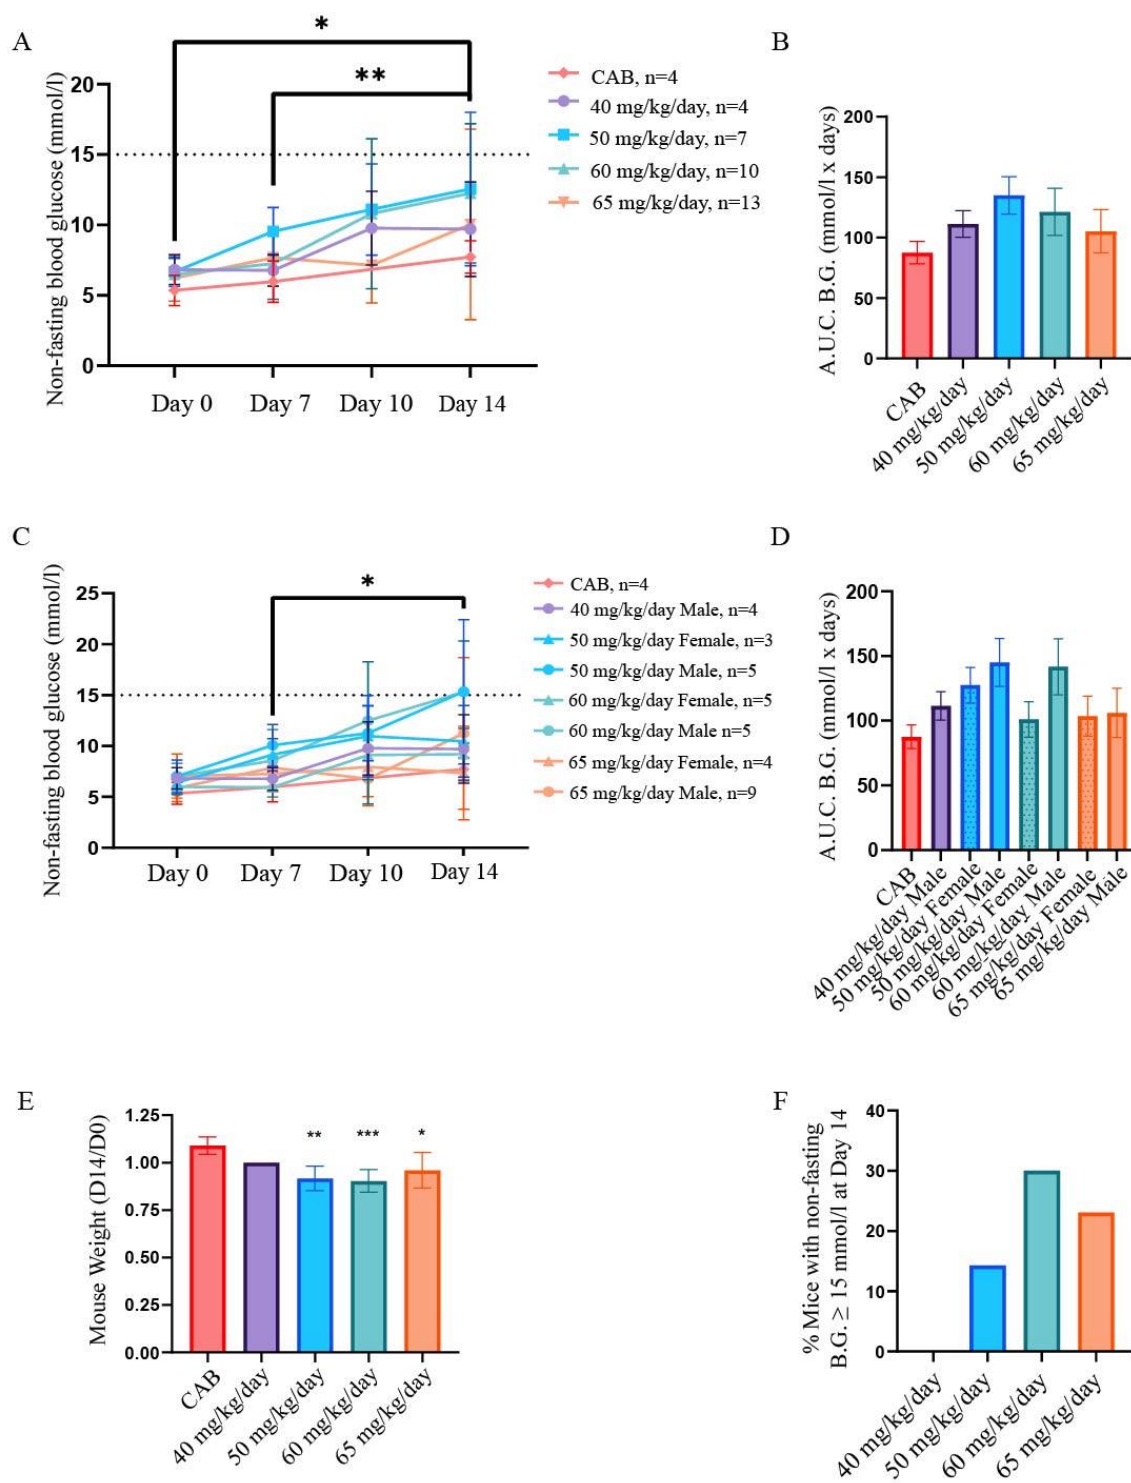

Figure 2.11 STZ treatment (60 mg/kg/day x 5 days) of CK19-CreERT;Ai9(RCL-tdT) mice resulted in elevated glycemia (≥ 15 mmol/l) at Day 14. CK19-CreERT;Ai9(RCL-tdT) mice (8-12 weeks old) administered 40, 50, 60, or 65 mg/kg/day STZ for 5 consecutive days were assessed for non-fasting blood glucose and body weight at Days 0, 7, 10, and 14. **(A)** Treatment with 60 mg/kg/day of STZ (n=10) resulted in significantly increased non-fasting blood glucose levels at Day 14 compared to Day 0 and 7 values (*p<0.05 and **p<0.01, respectively). Treatment with 40 (n=4), 50 (n=7), or 65 mg/kg/day of STZ (n=13) showed no difference in non-fasting blood glucoses levels over time. **(B)** There were no significant differences in the areas under the curve between different concentrations of STZ administered compared to the CAB control. **(C)** Male mice administered 60 mg/kg/day STZ (n=5) had significantly increased non-fasting blood glucose levels at Day 14 compared to Day 7 (*p<0.05). There were no differences in non-fasting glucose levels for 40 mg/kg/day Males (n=4), 50 mg/kg/day Females (n=4), 50 mg/kg/day Males (n=3), 60 mg/kg/day Females (n=5), 65 mg/kg/day Females (n=4), and 65 mg/kg/day Males (n=9) over time. **(D)** There were no significant differences in the areas under the curve between each of the treatment concentrations (categorized by sex) compared to the CAB control. **(E)** Mice treated with 50 mg/kg/day, 60 mg/kg/day, or 65 mg/kg/day STZ exhibited weight loss (D14/D0) compared to CAB control mice. **(F)** Treatment with 60 mg/kg/day of STZ resulted in the highest proportion (30%) of mice with non-fasting blood glucose ≥ 15 mmol/l at Day 14. Data represent mean \pm standard error of the mean (SEM) for A.U.C. graphs and mean \pm SD for all remaining data. Non-fasting blood glucose curves were compared using a repeated measures two-way ANOVA followed by Tukey's multiple comparison test. Areas under blood glucose curves and changes in body weight were compared using a one-way ANOVA followed by Tukey's multiple comparison test (*p<0.05, **p<0.01, ***p<0.001).

2.3.8 STZ treatment reduced β -cell mass and islet number in CK19-CreERT;Ai9(RCL-tdT) mice

While STZ treatment seemed to modestly induce hyperglycemia in CK19-CreERT;Ai9(RCL-tdT) mice, histological analysis of the pancreas gives a better indication of β -cell death. CK19-CreERT;Ai9(RCL-tdT) mice treated with 40, 50, 60, or 65 mg/kg/day (Days 1-5) of STZ exhibited decreased β -cell mass and islet number (per mm²) at Day 14 compared to mice that did not receive STZ (Figure 2.12 F, G). Additionally, treatment with 60 mg/kg/day of STZ resulted in significantly fewer islets per mm² compared to treatment with 50 mg/kg/day. STZ treatment did not affect islet circumference compared to control mice (Figure 2.12 H). Based on the effects of 60 mg/kg/day STZ treatment on non-fasting blood glucose and β -cell mass, we decided this dose would be optimal for administration in CK19-CreERT;Ai9(RCL-tdT) mice prior to hMSC CM iPan injection.

2.3.9 Glucose tolerance was impaired in STZ-treated CK19-CreERT;Ai9(RCL-tdT) mice

Based on the collective effects of STZ treatment on non-fasting blood glucose, β -cell mass, and islet density, we chose 60 mg/kg/day as our optimal dose. A glucose tolerance test gives a better indication of real-time β -cell function in controlling blood glucose. CK19-CreERT;Ai9(RCL-tdT) mice treated with 60 mg/kg/day of STZ (Days 1-5) and CAB control mice were fasted for 3 hours on Day 14 before receiving bolus glucose (2 mg/kg) by i.p. injection. Blood glucose was assessed at 0, 5, 10, 15, 30, 45, 60, 90, and 120 minutes. STZ-treated mice demonstrated significantly increased blood glucose levels 120 minutes after bolus injection compared to CAB control mice (Figure 2.13A). STZ treated mice had significantly increased A.U.C. for blood glucose compared to CAB control mice, indicating impaired glucose tolerance (Figure 2.13B).

Figure 2.12 STZ treatment in CK19-CreERT;Ai9(RCL-tdT) mice decreased β -cell mass and islet number. CK19-CreERT;Ai9(RCL-tdT) mice (8-12 weeks old) were treated with 40 (n=4), 50 (n=7), 60 (n=10), or 65 (n=13) mg/kg/day of STZ by i.p. injection (Days 1-5). (A-E) Representative photomicrographs of frozen pancreas sections at Day 14 are shown. STZ treatment resulted in significantly decreased (F) β -cell mass and (G) number of islets per mm² compared to no STZ control mice. Treatment with 60 mg/kg/day resulted in significantly fewer islets per mm² compared to treatment with 50 mg/kg/day. (H) STZ treatment did not affect islet circumference compared to no STZ control mice. Data represent mean \pm SD compared using a one-way ANOVA followed by Tukey's multiple comparison test (**p<0.01, ***p<0.001).

Figure 2.13 Glucose tolerance was impaired in STZ-treated CK19-CreERT;Ai9(RCL-tdT) mice. CK19-CreERT;Ai9(RCL-tdT) (8-12 weeks old) were treated with 60 mg/kg/day of STZ (n=7) or CAB (n=4) for 5 consecutive days. On Day 14, mice were fasted for 3 hours before receiving bolus glucose (2 mg/kg) by i.p. injection and blood glucose was assessed at 0, 5, 10, 15, 30, 45, 60, 90, and 120 minutes. **(A)** STZ-treated mice had significantly increase blood glucose levels 120 minutes after bolus injection compared to mice injected with CAB. **(B)** STZ-treated mice demonstrated impaired glucose tolerance compared to mice injected with CAB. Data represent mean \pm SD compared using a two-way ANOVA followed by Tukey's multiple comparison test for the glucose tolerance time course. A.U.C. data represents mean \pm SEM compared using a student's t-test to compare area under the curve (* p <0.05).

2.3.10 tdTomato labels CK19-expressing cells in the pancreas of CK19-CreERT;Ai9(RCL-tdT) mice following tamoxifen administration

To assess whether this model specifically labels CK19⁺ cells and quantify labeling efficiency, CK19-CreERT;Ai9(RCL-tdT) mice were administered 6 mg tamoxifen by oral gavage 7 days before 60 mg/kg/day STZ treatment by i.p. injection for 5 consecutive days. Mouse pancreata were harvested at Days 0, 1, 7, and 14 and assessed for tdTomato and CK19 expression by flow cytometry and fluorescent microscopy. Mice treated with CAB (vehicle control) were euthanized on Day 14. Gated based on F.M.O. samples, live tdTomato⁺ cells labelled CK19-expressing pancreas cells at all timepoints in STZ-treated and CAB-treated mice (Figure 2.14A-D). To assess tdTomato labelling efficiency within the CK19⁺ population, live CK19⁺ cells were assessed for tdTomato expression based on the tdTomato FMO. tdTomato expression was observed in approximately 20% of CK19-expressing cells at each timepoint (Figure 2.14E-H). Future studies to optimize tamoxifen administration may improve CK19⁺ cell labeling efficiency, as the administered dose and repeated injection frequency may increase the efficiency of Cre recombinase activation in CK19-expressing cells²⁵⁰. tdTomato expression was not detected (<0.001%) when mice were administered corn oil without tamoxifen.

2.3.11 Pancreatic insulin expression diminished following STZ treatment in CK19-CreERT;Ai9(RCL-tdT) mice

While CK19-CreERT;Ai9(RCL-tdT) mice exhibited decreased β -cell mass and impaired glucose tolerance following STZ treatment, the proportion of insulin⁺ cells during STZ treatment is an important indicator of the effectiveness of STZ treatment. Mice were treated with 6 mg Tamoxifen followed by 7 days of rest. Mice were subsequently treated with 60 mg/kg/day of STZ (Days 1-5). At Days 0, 1, 7, and 14, pancreatic insulin expression was assessed by flow cytometry. Non-fasting blood glucose at Day 14 was not significantly increased compared to Day 0 (Figure 2.15C). The total proportion of insulin-expressing cells within the pancreas was significantly decreased at Days 7 and 14 compared to Day 0 (Figure 2.14A, D). Insulin expression within tdTomato⁺ cells was significantly reduced at Day 14 compared to Days 0 and 1 (Figure 2.15B,E).

Figure 2.14 tdTomato labeled CK19-expressing cells in the pancreas following tamoxifen treatment in CK19-CreERT;Ai9(RCL-tdT) mice. CK19-CreERT;Ai9(RCL-tdT) mice were treated with 6 mg Tamoxifen by oral gavage. After 7 days rest, mice were administered 60 mg/kg/day STZ by i.p. injection for 5 consecutive days. Mouse pancreata were harvested at Days 0, 1, 7, and 14 and assessed for tdTomato and CK19 expression by flow cytometry (n=4-7) and fluorescent microscopy. Mice treated with CAB (vehicle control) instead of STZ were sacrificed 14 days after the first day of treatment (n=4). **(A)** Live (Zombie-) tdTomato+ cells were assessed for CK19 expression based on the CK19 F.M.O samples. **(B)** Representative dot plot of CK19 expression vs. SSC-A (gated on live tdTomato+ cells). **(C)** Representative photomicrograph of tdTomato and CK19 expression. **(D)** tdTomato labelled CK19-expressing pancreatic ductal cells at all timepoints in STZ-treated and CAB mice. To assess tdTomato labelling efficiency within the CK19+ ductal population, live CK19+ cells were assessed for tdTomato expression based on the **(E)** tdTomato FMO. **(F)** Representative dot plot showing tdTomato expression in live CK19+ cells. **(G)** Representative photomicrograph showing CK19 and tdTomato expression in a duct. **(H)** tdTomato expression was observed in approximately 20% of CK19+ ductal cells at each timepoint.

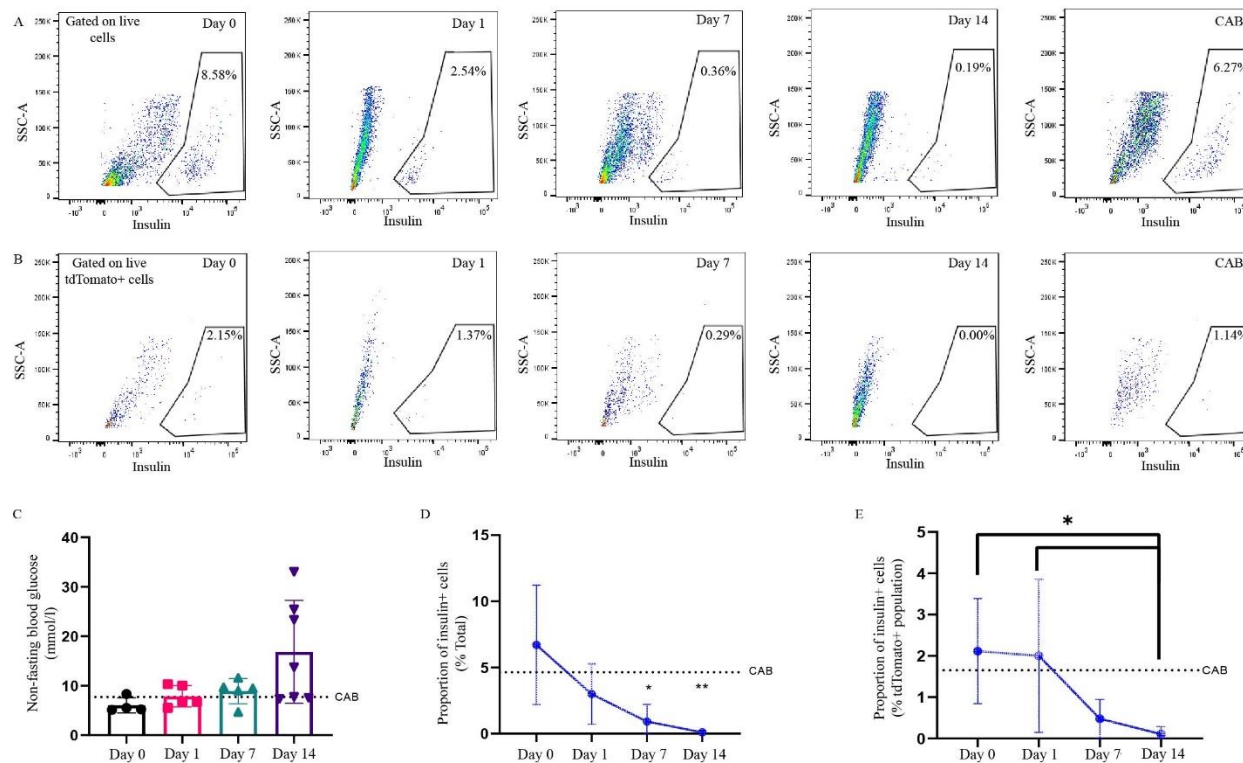

Figure 2.15 STZ treatment in CK19-CreERT;Ai9(RCL-tdT) mice decreased the proportion of insulin-expressing cells within the pancreas. CK19-CreERT;Ai9(RCL-tdT) mice were treated with 6 mg Tamoxifen by oral gavage. After 7 days rest, mice were treated with 60 mg/kg/day STZ by i.p. injection for 5 consecutive days. At Days 0, 1, 7, and 14, pancreatic insulin expression was assessed by flow cytometry (n=4-7). **(A)** Representative dot plots for insulin vs. SSC-A (gated on live cells) at each timepoint and CAB control mice are shown. **(B)** Representative dot plots for insulin vs. SSC-A (gated on live tdTomato+ cells) at each timepoint and CAB control mice are shown. **(C)** Non-fasting blood glucose at Day 14 was not significantly different compared to Day 0. **(D)** Insulin-expressing β -cells at Days 7 and 14 were significantly decreased compared to Day 0. **(E)** Within tdTomato+ cells, the proportion of insulin+ β -cells was significantly decreased at Day 14 compared to Days 0 and 1. Data represent mean \pm SD compared using a one-way ANOVA followed by Tukey's multiple comparison test (* $p < 0.05$, ** $p < 0.01$).

2.3.12 STZ treatment increased the proportion of infiltrating CD45+ cells in the pancreas of CK19-CreERT;Ai9(RCL-tdT) mice

To further investigate whether leukocyte infiltration plays a role in STZ-mediated injury, pancreata from CK19-CreERT;Ai9(RCL-tdT) mice treated with Tamoxifen 7 days before STZ treatment (Days 1-5) were assessed for CD45 expression, a pan-leukocyte marker^{251,252}, by flow cytometry. The proportion of CD45+ cells in the pancreas was significantly increased at Days 1 and 7 compared to Day 0 (Figure 2.16A,D). Within CK19+ cells, the proportion of CD45+ cells was significantly increased at Day 7 compared to Days 0 and 14 (Figure 2.15B,E). Within the tdTomato+ cell population, the proportion of CD45+ cells was significantly increased at Day 7 compared to Day 0 (Figure 2.16C,F).

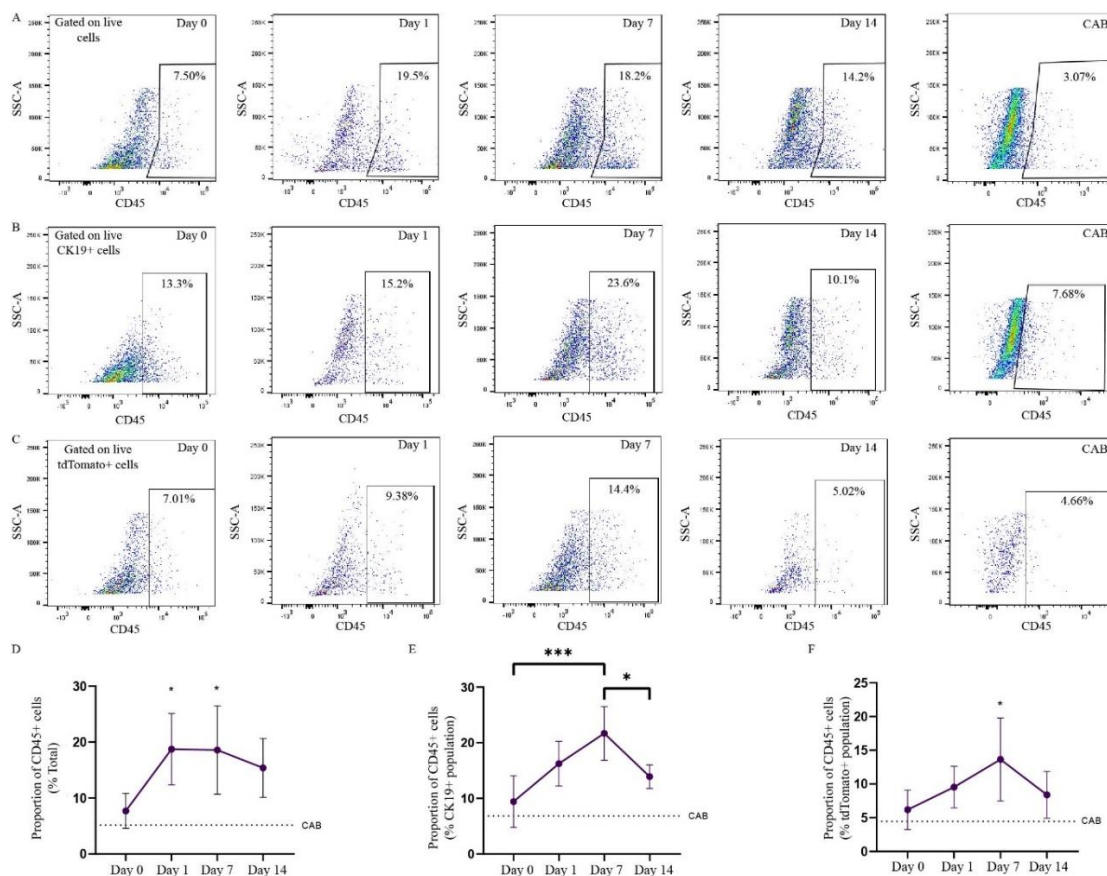

Figure 2.16 STZ treatment in CK19-CreERT;Ai9(RCL-tdT) mice increased the proportion of CD45+ cells in the pancreas. CK19-CreERT;Ai9(RCL-tdT) mice were treated with 6 mg Tamoxifen by oral gavage. After 7 days rest, mice were treated with 60 mg/kg/day STZ for 5 days. At 0, 1, 7, and 14 after STZ treatment, pancreatic CD45 expression was assessed by flow cytometry (n=4-7). **(A)** Representative dot plots for CD45 vs. SSC-A (gated on live cells) at each timepoint and for CAB control mice are shown. **(B)** Representative dot plots for CD45 vs SSC-A (gated on live CK19+ cells) at each timepoint and for CAB control mice are shown. **(C)** Representative dot plots for CD45 vs. SSC-A (gated on live tdTomato+ cells) at each time point and for CAB control mice are shown. **(D)** CD45+ leukocytes within the pancreas were significantly increased at Days 1 and 7 compared to Day 0. **(E)** Within CK19+ ductal cells, the proportion of CD45+ leukocytes was significantly increased at Day 7 compared to Days 0 and 14. **(F)** Within tdTomato+ cells, the proportion of CD45+ cells was significantly increased at Day 7 compared to Day 0. Data represent mean \pm SD compared using a one-way ANOVA followed by Tukey's multiple comparison test (* $p < 0.05$, *** $p < 0.001$).

2.4 Discussion

These studies demonstrated that hMSC CM increased CK19+ cell proliferation *in vitro* and characterized a lineage tracing mouse model to follow CK19+ cell fate following STZ-induced β -cell ablation followed by hMSC CM intrapancreatic injection in hyperglycemic mice. We utilized DBA lectin expression followed by serum supplemented culture as methodology to purify and culture viable cells enriched for CK19 expression²³¹. hMSC CM supplementation increased proliferation rates of CK19-expressing cells *in vitro*, although indication of mesenchymal or endocrine phenotype transition were not observed. We also characterized a lineage tracing mouse model that labels CK19-expressing cells in the pancreas following tamoxifen administration. Low-dose STZ treatment for 5 days induced hyperglycemia and diminished the insulin+ population within the pancreas. Collectively, these data suggest that hMSC CM positively impacts the growth kinetics of CK19-expressing cells *in vitro* and that CK19-CreERT;Ai9(RCL-tdT) mice may be used in future experiments to assess the contribution of CK19-expressing cells during islet regeneration following hMSC CM intrapancreatic injection in hyperglycemic mice.

While DBA lectin+ cells exhibited ~40% CK19 expression as assessed by flow cytometry, subsequent culture in complete PDC media further enriched for CK19 expression within this population (\approx 83% purity). Thus, this purification and culture process represents a reliable methodology to culture viable mouse pancreatic cells enriched for CK19 expression. hMSC CM supplementation into the culture media of DBA lectin+ cells isolated from healthy mice increased their proliferative response at 2 days, but no difference was observed at 5 days. This increase in proliferation was not observed in cell cultures from STZ-treated mice. The MSC secretome, comprised of soluble factors and extracellular vesicles, contains immunomodulatory, anti-apoptotic, pro-angiogenic, proliferative, and growth factors that facilitate tissue repair^{187,190–192}. hMSC CM has previously been shown to improve viability and migratory capacity of a human proximal tubular epithelial cell line following toxic chemical exposure, showcasing its protective effects on cells exposed to harsh environments including chemical treatment and cell culture assays²⁵³. Protective effects of hMSC CM, including enhanced survival, proliferation, or immunodulatory effects, has also been observed in endothelial cell, synovial explant, and microglia cultures^{254–256}. Interestingly, cultured CK19+ cells isolated from healthy mice exhibited higher rates of proliferation compared to cells isolated from STZ-treated mice. While the effects

of STZ treatment on pancreatic β -cells have been well characterized, phenotypic and functional changes in non-endocrine pancreatic cells, including the duct and acinar cells, and the ability of STZ to indirectly impact islet regeneration following β -cell destruction has not been reported. Further characterization of these phenotypic changes on non-endocrine cell populations, such as the expression of cell cycle regulators or EMT markers, could reveal additional cellular targets that contribute to pancreatic repair in hyperglycemic mice.

Mesenchymal or endocrine phenotype transition was not observed in cultures of DBA lectin+ cells from healthy or STZ-treated mice after 2, 4, or 7 days of cultured with hMSC CM. Further evaluation of phenotypic changes should be conducted in a 3-dimensional culture environment (e.g. cells suspended in collagen spheres) and transcriptome analysis of cell cycle, mesenchymal, and endocrine cell regulators should be investigated. Evidence for MSC CM modulation of differentiation following culture supplementation has been reported. hMSC CM has previously been shown to enhance chondrogenic, osteogenic, and hematopoietic differentiation in hESC cultures^{257,258}. Culture supplementation with MSC CM also upregulated expression of cardiomyocyte-related genes in cardiac progenitor cells²⁵⁹.

To evaluate the contribution of CK19-expressing cells in hMSC CM induced islet regeneration, we first aimed to develop and characterize a model to follow the fate of CK19-expressing cells within the pancreas. We used CK19-CreERT;Ai9(RCL-tdT) mice, which utilize tamoxifen pulse-chase labelling of CK19+ cells^{221,222}. A single tamoxifen treatment (6 mg) was sufficient to induce specific labelling of CK19-expressing cells in the pancreas one-week post-administration. Absence of tdTomato detection following corn oil vehicle control administration indicated that the CK19-CreERT promoter was not leaky. tdTomato labelling efficiency of CK19+ cells was approximately 20% across time. Further optimization of tamoxifen dosage (e.g. multiple administrations) may increase labeling efficiency. tdTomato labelling and promoter leakiness should also be assessed over a long-term period (e.g. 42 days) when characterizing hMSC CM-induced islet regeneration in these mice.

As CK19-CreERT;Ai9(RCL-tdT) mice possess active DNA-dependent protein kinase (DNA-PK), a DNA repair enzyme which is truncated and inactive in NOD/SCID mice^{260,261}, we hypothesized that a higher STZ dose would be required to induce hyperglycemia and loss of β -cell mass compared to the 35 mg/kg/day administered to NOD/SCID mice, as greater STZ sensitivity has been reported in NOD/SCID mice which lack functional T-cells²⁶². Consistent induction of severe hyperglycemia was difficult to achieve in CK19-CreERT;Ai9(RCL-tdT) mice. Treatment with 60 mg/kg/day for 5 consecutive days caused the greatest proportion of mice to become hyperglycemic (≥ 15 mmol/l non-fasting blood glucose) by Day 14. These mice exhibited decreased β -cell mass and islet density with no change in islet circumference, compared to control mice, and demonstrated impaired glucose tolerance following glucose bolus injection. Similarly, pancreatic biopsies from patients with T1D exhibit decreased islet density, while islet size was maintained compared to healthy subjects²⁶³. While there were some mice who did not become hyperglycemic, those considered suitable for hMSC CM injection will have non-fasting blood glucose levels between 15 and 25 mmol/l at Day 14.

Along with pancreatic β -cell loss, insulin+ cells within the pancreas were significantly decreased at Days 7 and 14. Similarly, within the tdTomato+ cell population, the frequency of insulin+ cells was diminished over time and were rare at Day 14 ($< 0.5\%$). This indicates that STZ treatment was successful in mediating β -cell destruction, and that emergence of insulin-expressing tdTomato+ cells following hMSC CM iPan injection, if absent in vehicle control mice, could truly be attributed to the regenerative microenvironment of the hMSC secretome in future experiments.

Additionally, STZ treatment induced leukocyte infiltration in mice. While NOD/SCID mice treated with 35 mg/kg/day STZ demonstrated a stable proportion of CD45+ cells within the pancreas, F4/80 upregulation at Day 10 indicated macrophage differentiation in response to increased β -cell apoptosis. Within CK19+ cells, an increase in F4/80+ cells on the last day of STZ treatment (Day 5) may indicate macrophage infiltration in response to pancreatic injury. Treatment of CK19-CreERT;Ai9(RCL-tdT) mice with 60 mg/kg/day of STZ induced pancreatic infiltration of CD45+ cells at Days 1 and 7. Within CK19+ and tdTomato+ cells, CD45+ leukocyte infiltration at Day 7 was observed, indicating possible interactions between leukocytes and pancreatic epithelial cells in response to STZ treatment. Future studies investigating leukocyte subpopulation breakdowns (e.g. macrophages, T-cells) during STZ-induced CD45+ cell infiltration will provide

insight into cellular phenotypes mediating the immune response. Macrophage and T-cell islet infiltration and subsequent release of inflammatory cytokines, including IL-1 β , IFN- γ , and TNF- α , mark key steps in diabetes pathogenesis resulting in β -cell destruction^{22,56-61}. Macrophages play a crucial role in tissue repair in response to injury or stress. During inflammation, macrophages secrete chemotactic factors to recruit immune cells and clear cellular debris from apoptotic cells via phagocytosis²⁶⁴. Evidence for pancreatic macrophage infiltration following STZ treatment has been reported²⁶⁵⁻²⁶⁷. While macrophages normally play an anti-inflammatory role in tissue repair, phagocytosis of apoptotic β -cells and elevated blood glucose levels promote a proinflammatory macrophage phenotype, potentially tipping the balance to favour β -cell destruction over regeneration^{268,269}. T-cell dependent Class II MHC antigen expression and subsequent pancreatic T-cell infiltration has been demonstrated in mice following multiple low dose STZ treatment^{270,271}. Infiltrating T-cells increase INF- γ release, further mediating inflammation and destruction within the pancreas²⁷¹. Thus, macrophages and T-cells represent key targets in attenuating inflammation and destruction in response to β -cell injury, and their regulation may play an important role in developing a regenerative microenvironment to promote islet regeneration.

In summary, these studies show increased proliferation of hMSC CM supplemented murine ductal cells *in vitro* and provide proof-of-concept characterization of CK19-CreERT;Ai9(RCL-tdT) mice during STZ treatment *in vivo*. The CK19-CreERT;Ai9(RCL-tdT) mouse model represents a valuable tool that required characterization prior to use in future studies to follow the fate of CK19-expressing cells during hMSC CM induced islet regeneration. Future studies, including optimization of tamoxifen treatment and in-depth characterization of pancreatic leukocyte infiltration in response to STZ treatment, will further solidify CK19-CreERT;Ai9(RCL-tdT) mice as a sound model for CK19+ cell lineage tracing and identify additional potential cellular targets to maximize islet regeneration, respectively. These studies ultimately aid in developing a cell-free regenerative therapy to stimulate islet regeneration to treat patients with diabetes.

3.0 Discussion

3.1 Summary

The primary objective of this research was to determine the effects of hMSC CM on murine ductal cells *in vitro* and to characterize a lineage tracing mouse model for the future assessment of CK19-expressing cell contribution to hMSC CM stimulated islet regeneration *in vivo*. We have previously shown that iPan injection of Wnt+ hMSC CM reliably reduces systemic blood glucose and rescues β -cell mass in hyperglycemic mice by stimulating the formation of small ductal-associated islet clusters via paracrine signals in mice with STZ-mediated β -cell ablation^{198-200,207}. Bone marrow-derived hMSC (P4, 80% confluent) were cultured in serum-free media for 24h to generate Untreated, Wnt+, or Wnt- CM using pharmacological small molecule treatment. CK19+ cells from mouse pancreata, purified by DBA lectin+ FACS were cultured in basal DMEM/F-12 media supplemented with hMSC CM. CK19+ cells from healthy mice exhibited increased proliferation at 2 days in culture with either Untreated, Wnt+, or Wnt- hMSC CM compared to basal media alone. Although proliferation was diminished at 5 days after hMSC CM supplementation, we found that hMSC CM, irrespective of Wnt-pathway stimulation, secreted regenerative stimuli that support short-term proliferation of CK19+ cells *in vitro*. Notably, CK19+ cells isolated from STZ-treated mice did not exhibit increased proliferation compared to basal DMEM/F-12 at 2 or 5 days of culture. Indeed, CK19+ cells isolated from STZ-treated mouse pancreata exhibited less proliferation in culture compared to cells from healthy mice, suggesting STZ treatment changes CK19+ cell growth rates in subsequent culture. Finally, evidence of epithelial-to-mesenchymal transition and endocrine phenotype acquisition were not observed in hMSC CM supplemented cultures with or without STZ treatment.

Next, characterization of CK19-CreERT;Ai9(RCL-tdT) lineage tracing mice was conducted. A single dose of tamoxifen (6 mg) induced specific labeling (tdTomato+) of CK19+ cells within the pancreas. The labelling efficiency of CK19+ cells with tdTomato was approximately 20%. Low dose STZ treatment (60 mg/kg/day) for 5 consecutive days induced hyperglycemia by Day 14 and insulin+ cells within the pancreas were also diminished at Day 14, with a corresponding decrease in β -cell mass. Reduced islet density was observed, while average islet circumference remained unchanged after STZ treatment. STZ treatment also stimulated pancreatic infiltration of leukocytes, which was also reflected within the CK19+ and tdTomato+ cell populations as there was a higher proportion of CD45+ cells. This may indicate immune cell

targeting of these populations as an indirect consequence of STZ treatment. Similarly, treatment of NOD/SCID mice with low dose STZ (35 mg/kg/day for 5 consecutive days) also resulted in macrophage (F4/80+) infiltration into the pancreas. Collectively, these findings suggest that CK19-CreERT;Ai9(RCL-tdT) mice represent a suitable model to characterize CK19+ cell contribution to islet regeneration following iPan injection of hMSC CM in STZ-treated mice.

3.2 hMSC CM improved proliferation of murine CK19+ cell *in vitro*, irrespective of Wnt-pathway stimulation or inhibition

As observed by Kuljanin *et al.*²⁰⁸, treatment of hMSC with CHIR99021 ($\geq 10 \mu\text{M}$) increased intracellular β -catenin levels without impacting hMSC viability, indicating Wnt-pathway stimulation was achieved. However, hMSC treatment with IWR-1 did not reduce intracellular β -catenin levels, contrary to previous observations using exclusively regenerative hMSC samples²⁰⁸. Low baseline levels of β -catenin/Wnt-pathway signaling in these non-regenerative hMSC samples may possibly contribute to this lack of observed downregulation and suggests that the Wnt-pathway was not active in all cultured hMSC samples.

Isolation of DBA lectin+ cells from mouse pancreata, followed by culture in complete PDC media proved effective in purifying viable CK19+ cells (~83% CK19+/DAPI+). As CK19 is an intracellular marker requiring antibody labeling, cells must be fixed and permeabilized to visualize or isolate CK19+ cells. As a surrogate marker for viable CK19+ ductal epithelial cells^{240,272}, DBA lectin, which specifically labels the α -linked N-acetylgalactosamine carbohydrate moiety, enriched 2-fold for viable CK19+ cells²³³. Further purification was achieved by culturing DBA lectin+ cells in complete PDC media as outlined by Reichert *et al.*²³¹. While supplementation of DBA lectin+ cells with hMSC CM, irrespective of Wnt-pathway stimulation or inhibition, improved proliferation of CK19+ cells at Day 2 compared to basal DMEM/F-12, this proliferative effect was diminished at Day 5. hMSC CM supplementation of DBA lectin+ cells isolated from STZ treated mice did not significantly change CK19+ cell proliferative frequencies. hMSC CM contains a combination of secreted factors and extracellular vesicles that commonly exhibit proliferative, pro-survival, and immunomodulatory effects to facilitate tissue repair^{187,190-192}. Previous studies have shown that the hMSC secreted factors, such as PDGF- β , IL-6, Erk1/2 pathway activators, VEGF,

and monocyte chemoattractant protein 1, can contribute to enhanced proliferation in co-culture with multiple cell types²⁷³⁻²⁷⁵. hMSC CM supplementation can increase survival and proliferation in endothelial cell, synovial explant, and microglia cell cultures²⁵⁴⁻²⁵⁶. hMSC CM supplementation has also been reported to improve culture efficiency of epithelial cells from the human proximal tubule and increased cell viability and migratory capacity following toxic chemical exposure²⁵³. Interestingly, pancreatic ductal cell proliferation rate is increased in obese individuals and in patients with T2D 10-fold and 4-fold, respectively²⁷⁶. Based on our previous observations of increased islet/ductal association after intrapancreatic hMSC CM injection²⁰⁷, this compensatory proliferative mechanism, stimulated by the presence of regenerative effectors, may contribute to murine islet regeneration *in situ*. Interestingly, CK19+ cells isolated from STZ-treated mouse pancreata exhibited less proliferation compared to cells from healthy mice across conditions. While the effects of STZ treatment on pancreatic β -cells have been well characterized, phenotypic and functional changes in nearby pancreatic cells, including the duct and acinar cells, and the ability of STZ to indirectly impact islet regeneration following β -cell destruction has not been reported. Further characterization of these phenotypic changes on non-endocrine cell populations, such as the expression of cell cycle regulators or EMT markers, could reveal additional cellular targets that contribute to pancreatic repair in hyperglycemic mice.

Studies conducted by the Collombat and Bonner-Weir groups suggest that islet regeneration involves EMT of duct-associated facultative progenitors followed by α - then β -cell endocrine transition^{18,19,148,153,154,156,160,277,278}. To investigate whether hMSC CM could stimulate phenotype transition of murine CK19+ cells *in vitro*, we looked for evidence of vimentin or glucagon/insulin expression during short-term cell culture. CK19 and vimentin co-localization was not observed 2, 4, or 7 days after hMSC CM supplementation. Additionally, CK19+ cells with glucagon or insulin co-localization was also not observed at each timepoint. Further evaluation of phenotypic changes should be conducted in a 3-dimensional culture environment (e.g. cells suspended in collagen spheres), which more closely mimics native tissue metabolic responses²⁷⁹. Transcriptome analyses of cell cycle, mesenchymal, and endocrine cell regulators should also be investigated in future studies. Evidence of hMSC CM-directed differentiation has been previously observed. hMSC CM has been shown to enhance differentiation of undifferentiated hESC into chondrogenic, osteogenic, and hematopoietic lineages^{257,258}. Evidence of enhanced cardiac

progenitor cell differentiation into cardiomyocytes based on upregulation of lineage-specific genes has also been reported²⁵⁹. Additionally, further investigation into hMSC-mediated improvement of functional outcomes in models of central nervous system injury through trophic effects revealed that hMSC culture supplementation selectively promoted neuronal stem cell differentiation into neurons and oligodendrocytes²⁸⁰. Thus, enhanced differentiation of a putative, pancreas-derived, facultative stem cell population *in vivo* following tissue injury seems plausible given regenerative signals provided by hMSC CM. While we have previously shown that Wnt+ hMSC CM reliably rescues hyperglycemia and β -cell mass following STZ-mediated ablation, the contribution of β -cell proliferation alone could not explain this robust improvement, while neoislet budding from pancreatic ducts seemed common²⁰⁷. Given this evidence, it is plausible that hMSC CM may stimulate differentiation of facultative progenitors within the pancreas, and cells within the ducts (CK19+) represent a strong candidate. While differentiation of CK19+ cells into endocrine cells was not observed *in vitro* following hMSC CM supplementation, evaluation of their contribution to islet regeneration in their native tissue environment *in vivo* will provide deeper insight into whether this population represents a cell responsive to hMSC secreted signals.

3.3 CK19-CreERT;Ai9(RCL-tdT) mice represent a strong model to characterize CK19+ cell contribution to islet regeneration

Lineage tracing mouse models which use lineage-specific promoters can label and permit long-term fate tracking even if phenotype transition or differentiation occurs. We used the CK19-CreERT;Ai9(RCL-tdT) mouse model to label CK19-expressing cells following tamoxifen administration. First described by Means *et al.*, the tamoxifen-inducible Cre-ERT was knocked into the CK19 locus²²¹. Tamoxifen administration in postnatal mice induced labeling in a wide array of epithelial populations, including pancreatic ducts, hepatic ducts, stomach, and intestinal cells²²¹. The reporter Ai9(RCL-tdT) mouse line has shown strong native fluorescence when crossed with different Cre lines²²². Thus, we bred CK19-CreERT mice with Ai9(RCL-tdT) reporter mice to generate a mouse line that would label CK19+ cells with bright tdTomato fluorescence following tamoxifen administration. Single dose (6 mg p.o.) tamoxifen treatment induced labeling in CK19+ cells within the pancreas at one-week post-administration. Of the tdTomato+ cells, >90% were CK19+ by flow cytometry, indicating strong CK19-labeling

specificity. Administration of corn oil vehicle control (no tamoxifen) resulted in $< 0.001\%$ tdTomato⁺ cell detection, indicating that this Cre recombinase system was not leaky. Of the CK19⁺ cells detected, only 20% were tdTomato⁺ after a single injection of tamoxifen. Future studies to optimize tamoxifen administration may improve CK19⁺ cell labeling efficiency, as the administered dose and repeated injection frequency may increase the efficiency of Cre recombinase activation in CK19-expressing cells²⁵⁰. Higher tamoxifen dose, or multiple low doses, should maximize labeling in future studies and should permit localization of labelled cells during hMSC CM neoislet formation^{281,282}. Whether the CK19⁺ cell population directly contributes to neoislet formation or indirectly facilitates neoislet budding from an alternative lineage, labeling studies using this mouse model should be performed to determine the origins of islet regeneration. However, tamoxifen toxicity represents a challenge in lineage tracing models. High doses of tamoxifen have been shown to cause gastric epithelium and liver damage^{283,284}. Thus, the optimal tamoxifen dose should be that which induces maximal Cre activation without injury to the mice. Future studies are underway to determine this optimal dose. Additionally, as single-cell transcriptome analysis has suggested heterogeneity within the pancreatic ductal cell population, further investigation into differential expression of ductal cell markers, including CK19, within the tamoxifen labeled population would clarify the presence of a potential progenitor population¹⁴⁹.

Another aspect of the model we needed to assess prior to inducing hMSC CM mediated islet regeneration was hyperglycemia induction after STZ treatment. Previously, we have shown that administration of low dose STZ (35 mg/kg/day) for 5 consecutive days results in hyperglycemia (non-fasting blood glucose 15-25 mmol/l) and impaired glucose tolerance at Day 10 in NOD/SCID mice^{198-200,207,225,226}. Thus, we used a similar strategy administering STZ to C57BL/6 CK19-CreERT;Ai9(RCL-tdT) mice. Because CK19-CreERT;Ai9(RCL-tdT) mice are immunocompetent and contain intact DNA-PK, a DNA repair enzyme that confers the SCID phenotype when inactivated^{260,261}, we hypothesized that a higher STZ dose would be required to induce hyperglycemia, as greater STZ sensitivity has been reported in NOD/SCID mice²⁶². We found that 60 mg/kg/day STZ treatment for 5 days induced hyperglycemia and impaired glucose tolerance in 1/3 to 1/2 of the mice at Day 14. CAB control mice exhibited normoglycemia and normal glucose tolerance at Day 14. While not all the mice were hyperglycemic at Day 14, only mice that have non-fasting blood glucose values between 15 and 25 mmol/l will be used for hMSC

CM transplantation studies. Mice that received STZ treatment had decreased β -cell mass and islet density, while islet circumference remained unchanged.

Following with the trends seen in decreasing β -cell mass, the proportion of insulin+ cells in the pancreas decreased with time during the STZ treatment protocol. At Days 7 and 14 following the start of STZ treatment, the proportion of insulin+ cells within the pancreas had significantly decreased, indicating that the STZ treatment protocol was effective in achieving β -cell ablation. Additionally, insulin+ cells within the tdTomato+ cell population decreased with time following STZ treatment. Very low detection levels of insulin+ cells at Day 14 means that any observed tdTomato+/insulin+ cells following hMSC CM iPan injection, pending emergence of this population is not seen in PBS control mice, could be attributed to the islet regenerative effects of the hMSC secretome. Based on studies including those from the Collombat and Bonner-Weir groups, there has been growing support that ductal cells, or subpopulations within the ductal lineage, may serve as a facultative progenitor population to compensate for pancreatic injury or disease^{44,154,156}. In order to investigate whether hMSC CM stimulates this reprogramming, lineage tracing models, like the CK19-CreERT;Ai9(RCL-tdT) mice described in this study, will need to be utilized to assess the relative contributions of various pancreatic cell populations to islet regeneration. This study lays the groundwork to identify key pancreatic target populations to increase islet regenerative efficiency.

3.4 Leukocyte infiltration plays a role in STZ-mediated pancreatic injury

Apoptosis of β -cells in diabetes pathogenesis results from T-cell and macrophage islet infiltration and subsequent release of inflammatory cytokines, including IL-1 β , IFN- γ , and TNF- α which activate signalling pathways that mediate cell death^{22,56-61}. Macrophage and T-cell pancreatic infiltration has also been reported following STZ treatment^{265-267,270,271}. Treatment of NOD/SCID mice with low dose STZ resulted in increased F4/80+ macrophage specification within pancreatic CD45+ leukocytes. Additionally, treatment of immunocompetent CK19-CreERT;Ai9(RCL-tdT) mice with low dose STZ (60 mg/kg/day x 5 days) resulted in increased CD45+ leukocyte pancreatic infiltration. Macrophages play a crucial role in mediating tissue repair in response to injury or stress. While macrophages normally play an anti-inflammatory role to facilitate tissue repair following tissue insult, STZ treatment stimulates phagocytosis of apoptotic

β -cells, which polarizes macrophages towards a pro-inflammatory phenotype^{268,269}. Similarly, STZ stimulates T-cell pancreatic infiltration in immunocompetent mice and inflammatory cytokine release²⁷¹. Chronic inflammation is associated with the onset of diabetes and its complications^{83,285,286}. Upregulation of inflammatory cytokines, including IFN- γ , TNF- α , and IL-1 β are associated with increased reactive oxidative species production that play a significant role in β -cell apoptosis²⁸⁶. STZ treatment also increased CD45+ cell co-localization with CK19 and tdTomato, indicating that these cells may also be affected by the STZ-mediated inflammatory response. Further investigation into the specific leukocyte lineages that drive this observed infiltration will provide insight into the inflammatory mechanism at play and identify potential targets to prevent the progression of diabetic complications. Trials aimed at attenuating pro-inflammatory immunity, including anti-CD20 antibody^{287,288}, inflammatory cytokine antagonist^{289,290}, and anti-inflammatory pharmacological agent^{291–295} administration have shown some success in attenuating β -cell apoptosis and symptoms. Thus, dampening the pro-inflammatory immune response mediated by macrophages and T-cells may represent a promising approach to slow disease progression in diabetes pathogenesis, reduce complications, and create a regenerative microenvironment to facilitate tissue repair.

It is well-established that the hMSC secretome exhibits immunomodulatory properties which have shown some success in treating immune disorders, including graft versus host disease^{296–298} and models of multiple sclerosis^{299–302}. Immunomodulatory functions of MSC include promotion of an anti-inflammatory macrophage phenotype, macrophage homing to the site of injury, limiting mast cell degranulation, inhibition of lymphocyte proliferation, decreasing lymphocyte pro-inflammatory cytokine synthesis, and increasing lymphocyte anti-inflammatory cytokine synthesis¹⁸⁰. While we've previously shown that Wnt+ hMSC CM injection provides a regenerative microenvironment that stimulates islet regeneration in the NOD/SCID mouse, it is possible that the immunomodulatory properties secreted by Wnt+ hMSC may also play a role in promoting tissue repair over progressive destruction. Further investigation into the hMSC secreted contents that mediate immune modulation may provide insight into strategies to prevent disease progression following early diagnosis.

3.5 Clinical Implications

Our data characterizes an immunocompetent lineage tracing mouse model that can be used to determine the contribution of CK19+ ductal cells to hMSC CM stimulated islet regeneration. hMSC are readily available and can be expanded efficiently in culture. For hMSC CM to be used in a clinical setting, production and expansion of hMSC may need to be scaled up to generate an appropriate dose. hMSC CM generated in serum-free culture conditions represents a cell-free mixture in which individual factors that are essential for islet regeneration can be identified to produce a therapy without the need for cellular purification and expansion. As Wnt-stimulation of hMSC in culture generates CM that consistently induces reduced hyperglycemia and β -cell rescue, we can circumvent the donor-dependent regenerative variability previously observed by pharmacological stimulation of the Wnt-pathway. However, since the hMSC secretome contains such a wide variety of factors that may be implicated in islet regeneration and immunomodulation, identification of individual essential components may prove to be challenging and labour intensive. While a single injection into hyperglycemic mice early in disease progression provides long term therapeutic effects, translation to a clinical setting may require multiple treatments. Additionally, characterization of β -cell regenerative ability in aged mice (>10 months) will provide further insight into hMSC CM clinical potential for older patients with diabetes.

The CK19-CreERT;Ai9(RCL-tdT) mouse model described in these studies comes from a C57BL/6 background strain. Previously, we have demonstrated islet regeneration in NOD/SCID mice, which lack functional T- and B-cells, exhibit low natural killer cell activity, and have reduced antigen-presenting cell function³⁰³. While NOD/SCID mice previously allowed us to transplant cells without immune rejection, now that we are using a cell-free agent, we can use an immunocompetent mouse model which is more applicable to the clinical setting. The progression of both T1D and T2D involves aberrant immune system activation or inflammation, so an immunocompetent model to characterize treatment with hMSC CM alongside the associated innate and adaptive immune responses is essential if we are looking towards clinical application. Apoptosis of β -cells is mediated by islet infiltration by pro-inflammatory macrophages, as well as T-cells in the case of T1D, resulting in cytokine release and phagocytosis^{22,56-61,304,305}. Nonetheless, characterizing islet regeneration in CK19-CreERT;Ai9(RCL-tdT) mice will provide further insight into response to hMSC CM treatment in the presence of functioning immune cells.

Characterization of CK19-CreERT;Ai9(RCL-tdT) mice as a lineage tracing model to determine the contribution of CK19+ cells to islet regeneration following hMSC CM injection will aid in elucidating the cellular cascade leading to β -cell mass rescue. RNA-seq of human pancreata has revealed heterogeneity and intermediate stages within endocrine cell populations, which could indicate potential plasticity within the human pancreas^{149–152}. One hypothesis that has gained considerable traction in recent years is the presence of a facultative progenitor cell population which resides in the ductal tree^{44,118,153,154,156}. Following *Pax4*-mediated α - to β -cell transition, *Hnfl* β ⁺ duct-lining cells demonstrated transient activation of *Neurogenin 3*, an endocrine progenitor marker, before adopting an α - then β -cell phenotype and function^{19,154,156}. Misexpression of *Ngn3* in *Hnfl* β ⁺ cells stimulated reactivation of the endocrine lineage specification pathway, resulting in their transition into functional β -like cells in mice¹⁵⁴. Lending support to duct cell plasticity, 15% of insulin-expression β -cells, which were not associated with other islet cells, have been found in or budding from ductules, paralleling β -cell lineage specification processes in the developing pancreas¹⁶². Thus, characterization of CK19-CreERT;Ai9(RCL-tdT) mice, which represents a feasible model to study hMSC CM mediated islet regeneration, is a considerable step forward in testing this hypothesis and finding the ‘signal-receiving cell’.

Our study has some limitations that need to be addressed as we plan for clinical translation^{22,62–66}. Firstly, pathophysiology of T1D involves autoantibodies and autoimmune destruction of β -cells. However, our model involves chemical ablation of β -cells to induce hyperglycemia. Thus, our model does not address the autoimmune aspects of T1D that may actively delete regenerating β -cells. Additionally, this model does not address the obesity-induced insulin resistance characteristic of T2D, meaning obesity specific inflammatory cytokines and metabolites will not be present throughout our proposed studies. STZ treatment of CK19-CreERT;Ai9(RCL-tdT) mice results in weight loss compared to control mice, which must be monitored closely as hyperglycemia progresses. Additionally, while lineage tracing provides us with direct fate-mapping of CK19+ cells with negligible leakiness, increasing labeling efficiency to maximize the probability of observing duct-to- β -cell transition requires administration higher dosages of tamoxifen, which has the potential to cause gastric and liver complications^{283,284}.

3.6 Future Directions

This study showed that tamoxifen administration to CK19-CreERT;Ai9(RCL-tdT) mice specifically labeled CK19⁺ cells and that low dose STZ treatment can result in hyperglycemia, impaired glucose tolerance, and reduced β -cell mass. Our next steps in this investigation are to investigate whether hMSC CM can induce islet regeneration in an immunocompetent host to determine the contribution of CK19⁺ cells to neoislets. This protocol will require treatment with tamoxifen followed by a rest period, STZ injection (60 mg/kg/day for 5 days), hMSC CM iPan injection, blood glucose monitoring, and histological and flow cytometric analysis according to the proposed model and timelines outlined in Figure 3.1. Analysis of tdTomato⁺ cells by histology and flow cytometry during the islet regenerative process will be conducted to determine whether they have acquired endocrine phenotype and will provide definitive evidence of any possible CK19⁺ cell contribution to neoislets. Co-localization of tdTomato with β -cell markers including insulin, MafA, and Nkx6.1 on a single cell level by flow cytometry and confirmation by confocal microscopy would provide strong evidence if this event occurred. tdTomato co-localization with other pancreatic cell markers, including those for other endocrine cell types (α -cells, somatostatin cells, and PP cells), mesenchymal cells (e.g. vimentin), and acinar cells (e.g. elastase) should also be assessed to investigate other avenues of pancreatic plasticity.

Figure 3.1 Proposed experimental strategy for assessing ductal cell contribution to β -cell regeneration in CK19-CreERT;Ai9(RCL-tdT) mice. CK19-CreERT;Ai9(RCL-tdT) mice will be used to fate map ductal cells following tamoxifen administration (6 mg per os, Day -21). To induce hyperglycemia, mice will be treated with STZ (60 mg/kg/day i.p. injection, Days -14 to -10), and subsequently receive hMSC CM iPan injection (Untreated, Wnt+, or Wnt-) on Day 0. Mice will be monitored twice weekly for non-fasted blood glucose concentrations and euthanized at Days 0, 7, and 28 (n=6-8) to assess tdTomato⁺ cell contribution to β -cell regeneration by immunohistochemistry on frozen pancreas sections and flow cytometry on dissociated, fixed, and permeabilized pancreatic tissue. EdU will be injected i.p. (200 μ g/100 μ l) 24h prior to euthanasia to assess replication of ductal, α -, or β -cells with or without tdTomato labeling.

Whether CK19+ cells contribute to islet regeneration or not, we will subsequently assess the contribution of other pancreatic cell types. Based on the hypothesis of ductal-to- α -to- β -cell transition^{18,19,44,154,156}, we plan to also use the Glucagon-CreERT2 mouse line crossed with Ai9(RCL-tdT) reporter mice to map the fate of α -cells during hMSC CM induced β -cell regeneration³⁰⁶. The experimental strategy and timeline will mirror that presented for CK19-CreERT;Ai9(RCL-tdT) mice.

While hMSC CM is a more clinically applicable therapeutic option compared to cellular therapies, identification of the specific components of the hMSC secretome that mediate islet regeneration would provide further translational ability. Identification and optimization of these factors and their relative doses will help ensure uniformity and reproducibility as a treatment option to improve outcomes for patients with diabetes. To do this, proteomic analysis and RNA sequencing can be used to identify key differences between regenerative and non-regenerative hMSC CM and these factors can be modulated to determine whether they are essential to stimulate islet regeneration. Further understanding of the islet regenerative cascade leading to β -cell mass rescue and the key CM components that mediate this process can be used to generate a cell-free therapy, in combination with treatments to combat ongoing autoimmunity in the case of T1D or harmful metabolites in the case of T2D, to improve outcomes and β -cell functionality in patients with diabetes.

Curriculum Vitae

Section 1: University Education Background

Master of Science, Department of Physiology and Pharmacology (2018-Present)

The University of Western Ontario, London, ON

Thesis Title: Developing a model to assess the contribution of cytokeratin 19-expressing cells in multipotent stromal cell-induced islet regeneration

Bachelor of Medical Sciences, Honours Specialization in Physiology (2014-2018)

The University of Western Ontario, London, ON

Thesis Title: Identification of ductal-derived beta cell precursors stimulated by bone marrow multipotent stromal cells

Section 2: Research Experience

Master's Student, Dr. David Hess's Lab of Regenerative Medicine, Robarts Research Institute, Department of Physiology and Pharmacology, The University of Western Ontario, London, ON (2018-Present)

- I showed that the secreted contents (conditioned media) of human bone marrow-derived multipotent stromal cells increase proliferation of murine ductal cells *in vitro* and characterized a lineage tracing mouse model to follow the fate of cytokeratin 19-expressing cells following conditioned media injection.
- I performed cell purification preparation, cell culture expansion, immunofluorescence staining, and mouse handling and treatments, as well as analyses using flow cytometry and immunofluorescence/immunohistochemical imaging.

Summer Research Student, Dr. David Hess's Lab of Regenerative Medicine, Robarts Research Institute, London, ON (May 2018-August 2018)

- I digested pancreata from streptozotocin-treated mice to prepare for analysis by fluorescence activated cell sorting and subsequently cultured and stained purified cells by immunofluorescence.
- Cultured and expanded human bone marrow multipotent stromal cells and concentrated their conditioned media for experimental use.
- I cryosectioned and performed histological analysis on pancreatic tissue sections to image various cell markers.
- I reviewed relevant literature to develop experiments and stay up-to-date on the use of stem cells for pancreatic beta cell regeneration.

Physiology Undergraduate Honours Thesis, Dr. David Hess's Lab of Regenerative Medicine, Robarts Research Institute, Department of Physiology and Pharmacology, The University of Western Ontario, London, ON (September 2017-April 2018)

- I cultured and expanded human bone marrow multipotent stromal cells concentrated conditioned media for experimental use.
- I prepared mouse pancreatic ductal cell for isolation using fluorescence-activated cell sorting and subsequently cultured them for immunofluorescence analysis.
- I presented the results of my study and discussed how it impacts the current knowledge in the field on a scientific poster to colleagues and faculty members.

Physiology Laboratory Student, Department of Physiology and Pharmacology, The University of Western Ontario, London, ON (September 2016-April 2017)

- I clearly and concisely wrote a scientific report on the characteristics of conduction in the sciatic nerve of a pithed frog, muscle contraction of the human flexor digitorum superficialis, and interactions between the nervous and muscular systems in response to external stimuli by gathering information from laboratory experiments and relevant literature.
- I clearly articulated background information, methods, results, and the relevance of scientific experiments pertaining to visual smooth pursuit, oxygen consumption, and dexamethasone treatment on embryonic mouse tibiae in oral presentations using posters or PowerPoint presentations.

Summer Student Research Program Volunteer, Brampton Civic Hospital, Brampton, ON (June 2015-August 2015)

- I worked alongside the surgical department's clinical analyst to analyze outcome and efficiency data to brainstorm a new structure for the hospital's endoscopy department based on provincial funding guidelines

Section 3: University Research Presentations and Awards

Canada Graduate Scholarship-Master's, Canadian Institutes of Health Research (2019-2020; \$17,500)

London Health Research Day Poster Presentation, London, ON (2019)

- I presented my work on the effects of the secreted contents of human-derived stem cells on the growth kinetics and protein expression of isolated mouse pancreatic ductal cells in culture to attendees.

Physiology and Pharmacology Research Day Poster Presentation & Award in New Student Category, Department of Physiology and Pharmacology, The University of Western Ontario, London, ON (2018)

- I presented my work on the planned methodology and preliminary results for my Master's thesis project.
- I received an award in the 'New Student' category for my poster presentation.

Till & McCulloch Meetings Poster Presentation, Ottawa, ON (2018)

- I presented my work on the effects of the secreted contents of human-derived stem cells on the growth kinetics and physical make up of isolated mouse pancreatic ductal cell cultures at a national conference.
- I received a travel award from Stem Cell Network for my work to fund my attendance at the conference.

Dean's Honor List, The University of Western Ontario, London, ON (2015-2018)

Continuing Admission Scholarship, The University of Western Ontario, London, ON (2014-2017)

Section 4: Technical Research Experience

***In vivo* procedures:** mouse subcutaneous injection, mouse intramuscular injection, mouse intraperitoneal injection, rodent anesthesia, rodent aseptic surgical techniques, mouse oral gavage, mouse intracardiac blood collection

***In vitro* procedures:** tissue culture, cell immunotyping using flow cytometry, immunofluorescence/immunohistochemistry

Section 5: Teaching Experience

Teaching Assistant, Department of Physiology and Pharmacology, The University of Western Ontario, London, ON (2018-2020)

- I worked with a group of graduate students to plan and lead undergraduate physiology and pharmacology experiments to develop students' reasoning and communication skills, and gave ongoing feedback and support to students to assist in their academic and personal development.
- I participated in regular team meetings to practice ongoing improvement of the performance of teaching roles.

Kaplan MCAT Prep Course Instructor and Live Online 1:1 Tutor, Kaplan Test Prep, Toronto/London, ON (2017-2020)

- I created lesson plans and led interactive learning sessions tailored to student needs to help students develop skills required to be successful on the MCAT.
- I developed study plans for students based on their specific skill sets and goals.
- I communicated with students regularly via email to keep up-to-date on their progress in their study plan and on their well-being, and adapted their study strategies moving forward accordingly.

Leadership and Academic Mentorship Program Peer Mentor, The Student Success Centre, The University of Western Ontario, London, ON (2015-2017)

- I drew on personal experience in my university career to provide guidance and advice to first and second year students in the Medical Sciences program via email and personal meetings.
- I provided first and second year students with up-to-date notices of campus events to help them expand their communication and leadership skills and gain experience by getting involved in the campus community.
- I worked with a team to facilitate a first year Chemistry review session to help first year students prepare for an upcoming exam.

Tutor (Math and Science), Western Young Tutors Club, The University of Western Ontario, London, ON (2014-2017)

- I provided teaching support to high school students to improve their grades and develop a solid foundation of basic knowledge to be used in more advanced courses.
- I created lesson plans tailored to the specific learning styles of each student to aid in their development of the problem-solving skills.
